Receptor for advanced glycation end products · Streptococcus pneumoniae · Sepsis

Abstract
Streptococcus pneumoniae is one of the most common causes of sepsis. Sepsis is associated with the release of ‘damage-associated molecular patterns’ (DAMPs). The receptor for advanced glycation end products (RAGE) is a multiligand receptor, abundantly expressed in the lungs, that recognizes several of these DAMPs. Triggering of RAGE leads to activation of the NF-κB pathway and perpetuation of inflammation. Earlier investigations have shown that the absence of RAGE reduces inflammation and bacterial dissemination and increases survival in sepsis caused by S. pneumoniae pneumonia. We hypothesized that the detrimental role of RAGE depends on the level of RAGE expression in the primary organ of infection. By directly injecting S. pneumoniae intravenously, thereby circumventing the extensive RAGE-expressing lung, we here determined whether RAGE contributes to an adverse outcome of bacteremia or whether its role is restricted to primary lung infection. During late-stage infection (48 h), rage\textsuperscript{−/−} mice had an attenuated systemic inflammatory response, as reflected by lower plasma levels of proinflammatory cytokines, reduced endothelial cell activation (as measured by E-selectin levels) and less neutrophil accumulation in lung tissue. However, RAGE deficiency did not influence bacterial loads or survival in this model. In accordance, plasma markers for cell injury were similar in both mouse strains. These results demonstrate that while RAGE plays a harmful part in S. pneumoniae sepsis originating from the respiratory tract, this receptor has a limited role in the outcome of primary bloodstream infection by this pathogen.

Introduction
Sepsis is a leading cause of death and represents a major challenge in the care of critically ill patients [1, 2]. Streptococcus pneumoniae is a frequent cause of sepsis that, in the majority of cases, originates from a respiratory focus [3, 4]. At particular risk for developing pneumococcal sepsis is the expanding group of high-aged and immunocompromised patients. Together with the emergence of antibiotic resistance the burden of this disease is expected to grow in the future [4]. Hence, new treatment strategies must be explored to improve care of infections caused by S. pneumoniae.

Immunomodulating agents designed to attenuate the systemic hyperinflammation syndrome are a widely studied topic in sepsis research. In this field the receptor for advanced glycation end products (RAGE) has been implicated as a possible target considering its role in perpetuating inflammatory responses [5, 6]. RAGE is a member of the immunoglobulin superfamily of cell surface molecules [7, 8] and is expressed on a wide array of cell types. RAGE binds to Mac-1 on neutrophils [9], contributing to neutrophil recruitment, and to a number of endogenous molecules that are released upon cell stress or cell damage known as damage-associated molecular patterns (DAMPs). DAMPs that are recognized by RAGE include high-mobility group box 1 (HMGB1) and S100 proteins [5, 6]. Engagement of RAGE activates the NF-κB pathway, which in turn upregulates expression of RAGE, thus inducing sustained cellular inflammation and promoting cellular dysfunction and tissue damage [10, 11].

Several animal studies have shown that RAGE is critically involved in the deleterious effects of acute inflammatory disorders, including sepsis [12–16]. Deletion of the rage gene was initially found to protect against the lethal effects of septic shock in polymicrobial sepsis, which was associated with a strongly reduced activation of NF-κB in the peritoneum and lungs [12]. Our group previously investigated the role of RAGE in sepsis derived from S. pneumoniae pneumonia [14], showing increased RAGE expression in the lungs upon infection and a relatively protected phenotype of RAGE deficient (rage−/−) mice [14]. In accordance, independent investigations showed that anti-RAGE treatment improved outcome in invasive pneumococcal pneumonia [15]. However, RAGE inhibition may be ineffective or even harmful in mice [13, 16]. Engagement of RAGE activates the NF-κB pathway, which in turn upregulates expression of RAGE, thus inducing sustained cellular inflammation and promoting cellular dysfunction and tissue damage [10, 11].

In the setting of pneumonia caused by a highly virulent strain of S. pneumoniae, RAGE may contribute to enhanced pulmonary inflammation as a consequence of its abundant expression in the lungs [17], impairing the integrity of the blood-lung barrier [18], leading to enhanced bacterial dissemination and a worsened survival [14]. To investigate the role of RAGE in host defense during primary bacteremia, we directly injected S. pneumoniae into the tail vein in order to ‘bypass’ the established role of RAGE in the lungs during pneumonia-derived sepsis. Even though direct pneumococcal infection of the bloodstream (e.g. through blood transfusion) is not common [19], this study may help identify whether RAGE’s harmful role in pneumococcal sepsis is restricted to the pulmonary compartment. To investigate this, we challenged mice with the same pneumococcal strain – serotype 3, ATCC 6303 – as in the pneumonia study, allowing better comparisons. We demonstrate that RAGE amplifies the systemic inflammatory response, but does not impact on bacterial loads or survival during fulminant systemic infection with S. pneumoniae. These data demonstrate that RAGE is not critically involved in the outcome of lethal nonfocal pneumococcal sepsis and suggest that the detrimental effect of RAGE is primarily exerted in the pulmonary compartment.

Methods

Ethics Statement

Experiments were carried out in accordance with the Dutch Experiment on Animals Act and approved by the Animal Care and Use Committee of the University of Amsterdam (Permit No. DIX101223).

Mice

C57Bl/6 wild-type (Wt) mice were purchased from Charles River Laboratories Inc. (Maastricht, The Netherlands). Rage−/− mice, backcrossed >10 times to a C57Bl/6 background, were generated as described [12] and bred in the animal facility of the Academic Medical Center (Amsterdam, The Netherlands). The Animal Care and Use Committee of the University of Amsterdam approved all experiments.

Design

Sepsis was induced as previously described [20]. Mice were intravenously injected in the tail vein with 5 × 10^5 of S. pneumoniae serotype 3 (American Type Culture Collection 6303, Rockville, Md., USA) in a 200-μl saline solution (n = 7–8 per strain) and sacrificed 24 or 48 h thereafter or monitored in a survival study. Collection and handling of samples were done as previously described [20, 21]. In brief, blood was drawn into heparinized tubes and organs were removed aseptically and homogenized in 4 volumes of sterile isotonic saline using a tissue homogenizer (Biospec Products, Bartlesville, UK). To determine bacterial loads, 10-fold dilutions were plated on blood agar plates and incubated at 37°C for 16 h. Organ homogenates were processed for cytokine measurements as described [21].

Assays

Tumor necrosis factor (TNF)-α, interleukin (IL)-1β, IL-6, RAGE and E-selectin concentrations were measured in tissue homogenates using ELISAs (all R&D Systems, Minneapolis, Minn., USA). The detection limit of the RAGE ELISA was 62.5 pg/ml. Plasma TNF-α, IL-6 and IL-1β were measured by cytometric bead array flex set assay (BD Biosciences, San Jose, Calif., USA). Lactate dehydrogenase (LDH) and aspartate aminotransferase (AST) were measured in plasma with kits from Sigma-Aldrich (St. Louis, Mo., USA), using a Hitachi analyzer (Boehringer Mannheim, Mannheim, Germany).
Role of RAGE during S. pneumoniae Bacteremia

**Histology**
Lungs, spleens and livers were harvested for histologic examination after 24 and 48 h, fixed in 10% formaldehyde and embedded in paraffin. Four-micrometer-thick sections were used for stainings. For granulocyte staining, slides were deparaffinized and rehydrated using standard procedures. Endogenous peroxidase activity was quenched by a solution of 0.3% H₂O₂ in methanol. Slides were then digested by a solution of pepsin 0.025% (Sigma-Aldrich) in 0.1 M HCl. After being rinsed, the sections were incubated in Ultra V Block (Thermo Scientific, Fremont, Calif., USA) and then exposed to FITC-labeled anti-mouse Gr-1 monoclonal antibody (BD Pharmingen, San Diego, Calif., USA). After washes, slides were incubated with a rabbit anti-FITC antibody (Nuclilab, Ede, The Netherlands), rinsed again and developed using bright DAB (Immunologic, Duiven, The Netherlands), rinsed again and developed using methyl green (Sigma-Aldrich), hydrated and mounted in Permount (Histolab, Gothenburg, Sweden). Gr-1-stained slides were photographed with a microscope equipped with a digital camera (Leica CTR500, Leica Microsystems, Wetzlar, Germany). Ten random pictures were taken per slide. In these images Gr-1 positivity and total surface area were measured using Image J software (US National Institutes of Health, Bethesda, Md., USA; http://rsb.info.nih.gov/ij); the amount of Gr-1 positivity was expressed as a percentage of the total surface area. Immunostaining for RAGE was performed as previously described [14]. In short, paraffin slides were deparaffinized and rehydrated using standard procedures. Endogenous peroxidase activity was quenched using 1.5% H₂O₂ in PBS. Primary antibodies used were goat anti-mouse RAGE polyclonal antibodies (Neuromics, Edina, Minn., USA) and secondary antibodies were biotinylated rabbit anti-goat antibodies (DakoCytomation, Glostrup, Denmark). ABC solution (DakoCytomation) was used as the detection enzyme. DAB peroxidase (Sigma-Aldrich) was used as substrate for visualization. Counterstaining was performed with methyl green (Sigma-Aldrich).

**HMGBl Western Blot**
For Western blotting of HMGBl, plasma samples were diluted 8× in sodium dodecyl sulfate buffer, 2% β-mercaptoethanol. After heating, samples were run on a 15% polyacrylamide sodium dodecyl sulfate gel and subsequently transferred to blotting membrane polyvinylidene difluoride membranes (Pharmacia, Piscataway, N.J., USA). Following blocking with 5% nonfat dry milk proteins (Protifar from Nutricia, Zoetermeer, The Netherlands) in 0.1% Tween phosphate-buffered saline (PBS-T), membranes were probed with peroxidase-labeled secondary antibodies (Cell Signaling Technology, Danvers, Mass., USA) for 1 h at room temperature in 1% bovine serum albumin in PBS-T. After washing with PBS-T, membranes were incubated with Lumi-Light Plus Western Blotting Substrate (Roche, Mijdrecht, The Netherlands) and positive bands were detected using an LAS3000 Luminescent Image Analyzer dark box (Fujifilm, Tokyo, Japan). Image quantification was performed using AIDA Image analyzer software (Raytest, Straubenhardt, Germany).

**Statistical Analysis**
Data are presented as means ± standard error of the mean, unless indicated otherwise. Differences between rage−/− and Wt mice were analyzed by Mann-Whitney U test. Survival was compared by Kaplan-Meier analysis followed by a logrank test. Analyses were done using GraphPad Prism version 5.0 (Graphpad Software, San Diego, Calif., USA). Values of p < 0.05 were considered statistically significantly different.

**Results**

**Expression of RAGE and HMGB1 in S. pneumoniae Sepsis**
Previous investigations have established that RAGE is constitutively expressed in pulmonary tissue and that RAGE expression is enhanced during pneumonia [14, 17]. To determine whether primary bloodstream infection alters RAGE expression, we performed immunohistochemical stainings of RAGE in mouse lungs and spleens after intravenous infection with S. pneumoniae. In accordance with earlier investigations [13, 17], uninfected lungs extensively expressed RAGE, which was primarily present in the interalveolar septa showing an endothelial pattern (fig. 1a). RAGE was not present in bronchial epithelium. Forty-eight hours after infection, lungs showed similar expression of RAGE compared to lungs from naive mice (fig. 1b). Immunohistochemical analysis of RAGE in lung tissue from rage−/− mice (used as a negative control) confirmed the specificity of RAGE staining (fig. 1c). There was minimal RAGE staining in normal healthy spleens, which did not change after infection (data not shown).

As well as immunohistochemical stainings, we measured RAGE concentrations in lung, spleen and livers by ELISA. Interestingly, pulmonary RAGE concentrations tended to be lower 48 h after infection (median 22 μg/mg tissue) compared to naive lungs (median 40 μg/mg tissue; fig. 1d). Uninfected spleens and livers displayed relatively low concentrations of RAGE (median of 1.2 and 1.6 ng/mg tissue, respectively). Sepsis enhanced RAGE protein concentrations tenfold in livers, but hardly in spleens (fig. 1f). Plasma levels of soluble (s)RAGE remained below detection limits (data not shown).

To obtain insight into the systemic release of HMGBl, a ligand for RAGE [22], we performed a Western blot on plasma samples harvested 24 and 48 h after infection. At both time points, circulatory HMGBl was detected and elevated compared to uninfected mice (fig. 1g).
RAGE Does Not Affect Bacterial Outgrowth in a Lethal Model of Pneumococcal Sepsis

Earlier studies have shown that RAGE impairs the outcome of pneumococcal pneumonia: mice lacking RAGE had an improved survival together with lower pulmonary inflammation and bacterial loads [14]. Since RAGE is primarily expressed in the lungs, we wondered whether this detrimental role of RAGE is restricted to pneumococcal pneumonia. To examine this, we injected 500,000 colony-forming units (CFU) of the same pneumococcal strain into the tail vein of Wt and rage−/− mice and harvested lungs, blood, spleens and livers to determine bacterial loads. At 24 and 48 h postinfection, bacterial burdens were similar in all organs of both mouse strains (fig. 2). Forty-eight hours after infection, however, 3 out of 8 Wt mice had already died, suggesting that RAGE contributed to lethality in this model. Monitoring survival in a separate experiment did not reveal a statistically significant difference between Wt and rage−/− mice, although the latter mouse strain displayed a modest survival advantage (fig. 3).

RAGE Enhances Systemic Cytokine Production in S. pneumoniae Bacteremia

Upon binding of ligands, RAGE leads to sustained activation of NF-κB and upregulation of the RAGE receptor, thereby perpetuating inflammatory responses [11]. To determine the role of RAGE in inflammation during pneumococcal sepsis, we measured circulatory as well as organ cytokine (TNF-α, IL-1β, IL-6) levels 1 and 2 days postinfection. Twenty-four hours after infection, no differences were observed between mouse strains, while 48 h after infection, rage−/− mice had significantly lower levels of plas-
ma TNF-α and IL-6 (fig. 4a–c). Although RAGE is especially expressed in the lungs [17], no significant differences in pulmonary cytokine levels were observed between Wt and rage−/− mice (fig. 4d–f). In addition, RAGE did not influence cytokine concentrations in the spleen (fig. 4g–i).

**RAGE Does Not Impact on Cell Injury after Systemic Infection of S. pneumoniae**

Sustained cellular activation by RAGE may lead to cellular dysfunction and tissue damage [11]. To evaluate the role of RAGE in cellular injury in S. pneumoniae bacteremia, we measured plasma levels of LDH, a general cell injury marker and AST, a marker specific for liver injury. Relative to rage−/− mice, Wt mice did not differ in cell injury markers, suggesting that RAGE does not contribute to tissue damage in this model of pneumococcal infection (fig. 5).

**RAGE Enhances Neutrophil Recruitment to the Lungs**

Recruitment of leukocytes to infectious sites is an essential step in host defense. RAGE has been implicated to play a role in neutrophil recruitment possibly mediated by Mac-1 on neutrophils [9]. To investigate the role of RAGE in leukocyte recruitment to specific organs in nonfocal sepsis, we analyzed Gr-1 stainings in lung and spleen sections 48 h after infection. Lungs from rage−/− mice had a lower percentage of Gr-1 staining compared to Wt mice indicating lower pulmonary neutrophil numbers (fig. 6a, c, d). Gr-1 staining in the spleens was similar in Wt and rage−/− mice (fig. 6b). Together these data suggest that pulmonary RAGE is involved in directing neutrophils to the lungs in pneumococcal sepsis.

**RAGE Contributes to Endothelial Cell Activation**

To obtain insight in the contribution of RAGE to endothelial cell activation during sepsis, we measured E-se-
E-selectin levels did not differ between mouse strains in spleens at any time point (data not shown).

**Discussion**

*S. pneumoniae* is the most commonly isolated pathogen in pneumonia and an important causative organism in severe sepsis [3]. Invasive infection and accompanying inflammatory mechanisms can cause tissue damage that...
is associated with release of DAMPs, which are recognized by pattern recognition receptors (PRRs) and perpetuate inflammatory responses [23]. RAGE is a PRR that is primarily expressed in the lung and has been implicated to interact with several DAMPs including HMGB1. In the setting of sepsis originating from pneumococcal pneumonia, RAGE enhanced pulmonary inflammation, resulting in enhanced bacterial growth and dissemination, and a worsened survival [14]. In the current study, we directly infected Wt and rage−/− mice with pneumococci into the bloodstream. Although most cases of pneumococcal sepsis have a pulmonary focus [3, 4], this ex-

perperimental model was used to investigate the role of RAGE in *S. pneumoniae* sepsis independent from respiratory dissemination. We show that the presence of RAGE is associated with enhanced systemic inflammation, increased endothelial cell activation and higher neutrophil numbers in the lungs. However, RAGE did not influence bacterial loads or survival in this model of fulminant systemic *S. pneumoniae* infection. These results imply that while RAGE plays a harmful part in pneumococcal pneumonia [14, 15], this receptor does not play a critical role in the outcome of sepsis during primary bloodstream infection with this clinically relevant pathogen.

RAGE is abundantly expressed in normal healthy lungs and upregulated during *S. pneumoniae* pneumonia [14, 17, 24, 25]. In contrast to these earlier findings, we here observed a decreased expression of pulmonary RAGE in a model of intravenously induced pneumococcal sepsis. The pattern of RAGE staining, however, remained unchanged. Similarly to our finding, the level of pulmonary RAGE expression was found to decrease in other lung injury and pulmonary fibrosis models [26, 27]. In addition, RAGE was hardly detected in naïve or infected spleens and livers.

sRAGE, lacking the transmembrane and cytoplasmic domains [28], has been detected in human plasma. sRAGE levels are elevated and suggested to be a marker of outcome in patients with sepsis [29], pneumonia [30] and acute lung injury [31]. In this study, we were unable to detect sRAGE in plasma, which is in accordance with an earlier study measuring circulating sRAGE levels in diabetic mice [32]. To the best of our knowledge, plasma sRAGE levels have never been documented in mice. The commercially available ELISA kit we used in our study is designed to measure any murine form of extracellular domain of sRAGE species with a detection limit of 62.5 pg/ml. Our measurements in plasma samples did not exceed this detection limit, which could be a limitation of the method we used to measure this protein. We could, however, detect plasma HMGB1. The expression of HMGB1 was increased in *S. pneumoniae*-infected mice compared to uninfected mice. Together with several other endogenous ligands, HMGB1 interacts with RAGE [11]. When bound to other DAMPs, such as extracellular cell-free DNA, HMGB1 is able to produce an inflammatory stimulus through RAGE and other PRRs [22].

The binding of RAGE triggers multiple intracellular signaling pathways which result in the translocation of NF-κB and the transcription of proinflammatory proteins. Activation of the NF-κB pathway upregulates expression of RAGE, leading to sustained cellular inflammation and the promotion of cellular dysfunction and tissue damage [11]. In accordance, harmful effects of RAGE have been shown in models of endotoxic shock and sepsis [12, 33]. In line with these results, RAGE enhanced lung inflammation and worsened survival in sepsis originated from pneumococcal pneumonia [14]. In the present study, we found a reduced inflammatory response in *rage*–/– mice, as reflected by lower TNF-α and IL-6 levels in plasma, 48 h after infection. The effect of RAGE was likely underestimated since at this time point 3 out of 8 Wt mice had already died. Although this finding suggests that the presence of RAGE increases lethality in this model, in a formal survival study a statistically significant difference could not be demonstrated. It should be noted that the severity of this intravenous challenge model varies from experiment to experiment. Indeed, in preliminary pilot studies we observed an approximate 50% lethality in Wt mice after intravenous injection of the *S. pneumoniae* dose used in the current manuscript. This variance can be partly explained by the fact that for each experiment a fresh bacterial inoculum is prepared. This is why all experiments were strictly controlled, i.e. Wt and *rage*–/– mice were infected with the exact same inoculum at the same time. In accordance with the survival data presented here, the plasma concentrations of cell damage markers such as LDH and AST were similar in Wt and *rage*–/– mice after systemic pneumococcal infection. The discrepancy between lung and bloodstream infection suggests that the pulmonary compartment has a somewhat harmful role in pneumococcal sepsis pathophysiology. A similar finding was observed earlier in the outcome of a rabbit model of pneumosepsis [34]. Here it was demonstrated that pulmonary infection with a cytotoxic strain of *Pseudomonas aeruginosa* damaged the alveolar epithelium, allowing for proinflammatory mediators to leak into the systemic compartment, responsible for the signs of septic shock. Intriguingly, shock did not occur after systemic infection, even though bacteria were evidently present, establishing the crucial importance of tissue infection in the pathogenesis in this type of septic shock.

Targeting RAGE in sepsis models may impair antibacterial defense, as demonstrated in *Escherichia coli* peritonitis [13, 16] where *rage*–/– mice had higher bacterial loads compared to Wt mice. In pneumococcal pneumonia, conflicting results were observed, as *rage*–/– mice demonstrated lower bacterial loads [14], while the opposite was true when Wt mice were treated with an anti-RAGE antibody [15]. While using the same strain of the *S. pneumoniae* as in these former pneumonia studies, RAGE did...
but not affect bacterial outgrowth after intravenous injection of bacteria. The majority of bacteria entering the bloodstream are taken up by the liver [35], and several studies have shown that the spleen is particularly important in the systemic clearance of encapsulated *S. pneumoniae* [36, 37]. The fact that RAGE did not influence bacterial outgrowth in the systemic model of infection could be due to the fact that RAGE, in contrast to the lungs, is hardly detected in these organs. Of note, the pneumococcal strain used is highly virulent in mice, which corresponds with the fact that serotype 3 pneumococci are associated with severe infections in humans as well [38].

Several studies have implicated RAGE in leukocyte recruitment. RAGE has been identified as a binding partner for Mac-1 on neutrophils in static and flow in vitro conditions [9, 12, 39–41]. In vivo, *rage*–/– mice displayed a diminished number of inflammatory cells in the peritoneum after cecal ligation and puncture [12] and thioglycollate-induced peritonitis [9] and in the bronchoalveolar compartment after *S. pneumoniae* pneumonia [14]. Although there was no infectious focus in the current study, *rage*–/– mice remarkably demonstrated a reduced number of Gr-1-positive cells in lung tissue, indicating lower neutrophil counts in this organ. However, spleens demonstrated similar Gr-1 expression between Wt and *rage*–/– mice. Clearly, these different roles of RAGE in neutrophil accumulation in lungs and spleen may be related to the extent of RAGE expression, which is much higher in the former organ. RAGE in addition enhanced the extent of endothelial cell activation, as reflected by higher E-selectin levels in whole lung and plasma. The reduced expression of E-selectin in the lungs may have contributed to the diminished neutrophil recruitment in *rage*–/– mice [42].

In conclusion, our results show that *rage*–/– mice had a reduced systemic cytokine response, reduced endothelial cell activation and lower neutrophil numbers in the lungs in response to systemic *S. pneumoniae* infection. RAGE did not influence bacterial loads. The finding that RAGE deficiency did not impact on survival in spite of attenuated inflammation suggests that in this model systemic inflammation is not the cause of death or that inflammation was not reduced enough in *rage*–/– mice to alter survival. Taken together with previous studies on the role of RAGE in host defense against infection [5, 6], these data suggest that the impact of RAGE on the outcome of infectious disease depends on both the pathogen and the primary site of infection. In addition, the current data suggest that the harmful role of RAGE in *S. pneumoniae* infection is primarily exerted in the pulmonary compartment and not systemically.
