Abstract
Background/Aims: The loss of reproductive capacity during aging involves changes in the neural regulation of the hypothalamic gonadotropin-releasing hormone (GnRH) neurons controlling reproduction. This neuronal circuitry includes glutamate receptors on GnRH neurons. Previously, we reported an increase in the expression of the NR2b subunit protein of the NMDA receptor on GnRH neurons in middle-aged compared to young female rats. Here, we examined the functional implications of the NR2b subunit on the onset of reproductive aging, using an NR2b-specific antagonist ifenprodil.

Methods: Young (3–5 months) and middle-aged (10–13 months) female rats were ovariectomized (OVX), 17β-estradiol (E2) or vehicle (cholesterol) treated, and implanted with a jugular catheter. Serial blood sampling was undertaken every 10 min for 4 h, with ifenprodil (10 mg/kg) or vehicle injected (i.p.) after 1 h of baseline sampling. The pulsatile release of pituitary LH and levels of GnRH mRNA in hypothalamus were quantified as indices of the reproductive axis.

Results: Our results showed effects of ifenprodil on both endpoints. In OVX rats given cholesterol, neither age nor ifenprodil had any effects on LH release. In E2-treated rats, aging was associated with significant decreases in pulsatile LH release. Additionally, ifenprodil stimulated parameters of pulsatile LH release in both young and middle-aged animals. Ifenprodil had few effects on GnRH mRNA; the only significant effect of ifenprodil was found in the middle-aged, cholesterol group.

Conclusion: Together, these findings support a role for the NR2b subunit of the NMDAR in GnRH/LH regulation. Because most of these effects were exhibited on pituitary LH release in the absence of a concomitant change in GnRH gene expression, it is likely that NMDA receptors containing the NR2b subunit play a role in GnRH-induced LH release, independent of de novo GnRH gene expression.

Introduction

Excitatory amino acids play a major regulatory role in the neuronal release of gonadotropin-releasing hormone (GnRH) from the hypothalamus, and subsequently lu-
teinizing hormone (LH) from the pituitary gland, thereby affecting reproductive function. Glutamate is the most abundant excitatory amino acid in the brain, and acts via both N-methyl-D-aspartate (NMDA) and non-NMDA (AMPA and kainate) receptors to stimulate neuronal targets, including GnRH neurons [reviewed in 1]. NMDA and AMPA receptors have been co-localized on GnRH neurons [2–4], and there is abundant evidence for the activation or inhibition of GnRH/LH release in response to NMDA and non-NMDAR agonists and antagonists, respectively, both in vitro and in vivo [5–14]. This includes their involvement in the control of the pulsatile pattern of LH release [5, 9–11], which is necessary for normal physiologic function [15–17]. Thus, glutamate receptors are part of the neural circuitry that regulates reproductive neuroendocrine function.

During the transition to middle age, female rats exhibit a number of changes in their reproductive capacity, including a shift from a regular (4- to 5-day) estrous cycle to an irregular (>5-day) cycle and finally acyclicity [18, 19]. During this period, a decline in LH levels [20] and changes in GnRH/LH pulsatile release including decreases in LH amplitude and interpulse interval [21–23] can be detected. Additionally, the effect of age on GnRH gene expression is debated, as studies show increases, decreases and no change dependent upon the methodology used and hypothalamic nuclei assayed [reviewed in 24]. GnRH protein expression during this transition period also shows very little to no significant changes [2, 25–27]. This suggests that the major change to the reproductive axis during this time is not to the expression of GnRH neurons, but rather its regulation by the neural circuitry influencing its actions. Numerous neurotransmitters and neurotrophic factors act on the GnRH neuron, both directly and indirectly. These are also undergoing age-related changes, and thus affect functional alterations in the hypothalamic control of reproduction.

There is evidence that hypothalamic glutamate plays a role in these age-associated changes, both through changes in glutamate release [28] and through altered responsiveness of NMDARs [12] due to changes in glutamate’s interactions with NMDARs. The NMDAR-stimulated release of mean LH seen in young rats is attenuated in middle-aged females [14] and aged (21–23 months) males [12]. To the authors’ knowledge, effects of NMDAR inhibition on LH release have not been reported in an aging rat model. However, administration of the NMDAR antagonist AP-5 to adult gonadectomized male [5, 10] or female [11] rats results in a decline of LH pulse amplitude and mean levels in both males and females, as well as a decline of LH pulse frequency and interpulse interval in females. Thus, we suggest that age-associated changes in the expression or function of hypothalamic NMDARs contributes to alterations in GnRH/LH pulsatile release.

Effects of glutamate agonists and antagonists on GnRH neurons are also modified by the steroid hormone environment. There is substantial co-expression of the NMDAR with estrogen receptors in the hypothalamus and preoptic area, suggesting that glutamate and estrogens may act on the same target cells to influence GnRH neurons [29, 30]. In most studies, effects of NMDAR activation on GnRH neurons are enhanced in the presence of estradiol (E2) [31, 32].

In the present study, we focused on the role of one NMDAR subunit, NR2b, and its age-related regulation of pulsatile LH release in female rats. The choice of the NR2b subunit was based upon previous evidence showing that this subunit specifically undergoes developmental and age-associated increases in its expression on GnRH neurons [2, 33], and the NR2b gene is associated with a quantitative trait locus thought to be involved in the regulation of puberty in mice [34]. Along with their expression on GnRH cells, NMDARs are also abundantly expressed on non-GnRH neurons in the hypothalamus, including regions that regulate GnRH release, and these also undergo age-related changes [3, 30, 31]. Thus, effects of NMDAR activation on GnRH release involve both direct and indirect actions. Here, we used an NR2b-selective antagonist, ifenprodil, to assess the role of the NR2b subunit on GnRH activity in the context of aging (young vs. middle-aged) and hormone environment (ovariectomy plus vehicle or 17β-E2).

Methods

Animals

A total of 76 female Sprague-Dawley rats were used in this study, with 38 young (3–5 months) and 38 middle-aged (10–12 months). All were purchased from The University of Texas at Austin Animal Resource Center rat colony (Austin, Tex., USA), which contains animals received and bred from Harlan Sprague-Dawley, Inc. (Indianapolis, Ind., USA). Animals were group housed (2–3/cage) in a temperature-controlled room (21–22°C) with a 12 h light, 12 h dark reverse cycle (lights on at 01:00 h). Food (standard rat chow) and water were provided ad libitum. All animal protocols were conducted in accordance with the Guide for the Care and Use of Laboratory Animals [35] following protocols approved by The University of Texas at Austin IACUC.

Surgical Procedures

The cycling status of all young and middle-aged animals was first determined through examination of daily vaginal cytology.
observed for a minimum of 10 days. Rats were characterized as regularly cycling (4- to 5-day estrous cycles), irregularly cycling (6+ day estrous cycles) or acyclic (persistent estrus). Cycling animals were ovariectomized (OVX) at 10:00 h on diestrus (for young, regularly cycling and middle-aged, irregularly cycling animals). Acyclic rats were OVX on persistent estrus (middle-aged, acyclic animals). Surgeries were performed under isoflurane gas anesthesia and rats were treated postoperatively with 5 mg/kg Rimadyl. 4–6 weeks later, animals were subcutaneously implanted at 10:00 h with a Silastic capsule (capsule dimensions: inner diameter 1.96 mm; outer diameter 3.18 mm) containing either 5% 17β-estradiol/95% cholesterol (E2) or 100% cholesterol (Chol; Sigma-Aldrich, St. Louis, Mo., USA) as vehicle, under isoflurane anesthesia (day 0). Young animals received an implant 1.0 cm in length; middle-aged animals received an implant 1.5 cm in length. Different lengths were used to account for size differences associated with age differences [36]. Following surgery, animals were housed individually. Two days following hormone replacement (day 2), animals were implanted with a jugular catheter [modified from 37]. Rats were anesthetized with ketamine (90 mg/kg, i.p.) and xylazine (10 mg/kg, i.p.). A Silastic catheter (0.51 mm inner diameter, 0.94 mm outer diameter) was inserted into the right jugular vein and advanced into the right atrium. A cannula (Plastics One, Roanoke, Va., USA), located at the distal end of the catheter, was subcutaneously routed around the neck and out through an incision on the top of the head. Here, it was affixed to the skull with stainless steel screws and dental acrylic cement. Catheters were flushed daily and patency verified using 0.1 ml of 30 U/ml heparinized saline. In cases where the jugular catheter did not remain patent through serial blood sampling, the catheter was flushed with stainless steel screws and dental acrylic cement. Catheters were flushed daily and patency verified using 0.1 ml of 30 U/ml heparinized saline, 62 mg/ml Timentin. In cases where the jugular catheter did not remain patent through serial blood sampling, animals were given a new catheter in the left jugular vein (day 4) and serial blood draws were resumed on day 6. There was no effect of this process on any results.

**Serial Blood Sampling**

On day 4, from 10:00 to 14:00 h, animals were placed in aquaria divided into two chambers with no visual or tactile contact. Catheters were attached to St. Gobain tubing (inner diameter 0.508 mm; outer diameter 1.524 mm; VWR #63018–044), attached to a 22-gauge needle with 3-cs syringe filled with 5 U/ml heparinized saline. Syringes were suspended from the top of the aquaria, allowing the animals to move freely during serial blood sampling. 0.2 cc of blood was collected into heparinized microcentrifuge tubes (1,000 U/ml) every 10 min for 4 h. Following each collection, bloods were centrifuged at 6,000 g for later LH and estrogen radioimmunoassay. Brains were removed and the preoptic area-anterior hypothalamus (POA-AH) was dissected, as described previously [40]. Briefly, dissections were done using a cold, stainless steel brain matrix, flash-frozen on dry ice, and stored at –80°C.

**RNA Extraction for Real-Time PCR**

RNA was extracted from frozen POA-AH tissues using a well-established in-house double detergent lysis buffer system, adapted from Jakubowski and Roberts [40]. Briefly, tissues were homogenized via extrusion through a 22-gauge needle, treated with proteinase K, and RNA was extracted in phenol chloroform and precipitated in ethanol. Nuclear and cytoplasmic portions were separated using a two-buffer system. The cytoplasmic RNA of each animal was treated with DNase Free kit (Ambion, Austin, Tex., USA) according to manufacturer’s specification. RNA integrity was confirmed using a bioanalyzer (Agilent 2100) and the concentration determined using Nanodrop ND-1000. RNA was then stored at –80°C until use in real-time PCR.

**Real-Time PCR**

GnRH gene expression was determined in the POA-AH and normalized to a housekeeping gene, cyclophilin [41, 42]. A reverse transcriptase reaction was carried out using 2 μg of cytoplasmic RNA with Superscript II Reverse Transcriptase (Invitrogen, Carlsbad, Calif., USA), according to the manufacturer’s instructions. The product was stored at –20°C until use, at which time cDNA was diluted 1:5 before PCR reactions were performed. Real-time PCR was performed using the Stratagene Brilliant® qPCR master mix and were run on a Stratagene MX3000 (Stratagene, La Jolla, Calif., USA) using the following reaction parameters: 1 cycle at 95°C for 10 min followed by 45 cycles at 95°C for 30 s, 55°C for 1 min, and 72°C for 30 s. All reactions were run using primer and probe sequences developed and tested in house (GnRH) or as previously published (cyclophilin [41]) (IDT, Coralville IA Primers; Eurogentec) at concentrations listed in table 1. A validation experiment was performed for the GnRH and cyclophilin assays to ensure that the reaction efficiencies were comparable. Each product was run on a 3% agarose gel to confirm amplicon length and specificity. A no reverse transcriptase (no RT) control was run for each sample to determine if genomic contamination was present. Any samples containing significant contamination were discarded from analysis (ΔΔCt ≥ 10). A positive control was run on each plate to determine interassay variability.

Relative expression of GnRH mRNA levels, normalized to cyclophilin mRNA levels and calibrated with a positive control, was determined using the ΔΔ Ct method [43]. Samples were run in

NMDA-NR2b Receptors, GnRH Neurons, Estrogens and Aging

Neuroendocrinology 2008;87:129–141

131
triplicate and analyzed in duplicate to account for pipetting errors. Interassay variability was 9.0%.

Radioimmunoassay (RIA)
LH. LH in serum samples was determined in single samples using double antibody RIA. This RIA was performed using the rat LH RP-3 standard, iodinate and antibody from the National Hormone and Pituitary Program of the NIDDK (kindly provided by Dr. A.F. Parlow). Three assays were performed. The assay sensitivity was 0.03 ng/tube at 85% binding. The intraassay variability ranged from 3.6 to 12.3%. Interassay variability was 2.95%.

 Estradiol. E2 levels were determined in serum samples from trunk bloods when there was residual serum from the LH assay. The DSL ultrasensitive estradiol kit (DSL-4800, Diagnostic Systems Laboratories, Inc., Webster, Tex., USA) was used according to the included instructions. Samples were run in duplicate in a single assay. The intraassay variability was 2.8%.

Statistical Analysis
LH Pulse Analysis. A computer-based pulse detection method, Cluster, was used to analyze pulsatile release of LH [44]. This is available in the Pulse_XP software suite provided by Michael L. Johnston (University of Virginia, Va., USA). This algorithm identifies significant increases and decreases within a data set in relation to measurement error inclusive to experimental data. A moving nadir (referred to as a test nadir and defined as a cluster of points) of two points for test nadir were compared to two experimental points using pooled t-test to determine significant rises within the data set. The entire data set is examined for increases in significance through shifting of test nadir and experimental points by one sample. This continues through the entire series, and upon completion, the process moves in reverse to determine significant falls in the data. A peak is defined as a significant increase followed by a significant decrease, and thus a peak must be surrounded by nadirs on each side.

In this analysis, we used parameters suggested by the program developers. In brief, this includes 2 points used to define peaks and nadirs, a statistic of 2.75 for significant increases and 1.5 for significant decreases, and 2 degrees of freedom for sample mean [44]. Analyses include mean LH (average LH value for the entire experimental period from the second to the penultimate sample (see below)), pulse frequency (number of peaks) and amplitude (height of peaks), pulse width (in minutes) and area (defined as the product of the mean peak subtracted from the average of the pre- and post-peak nadirs multiplied by the peak width), interpeak intervals (between peak regions) and interpeak concentrations [44]. Significant changes in these variables were determined using one-way and two-way analysis of variance (ANOVA) and the Kruskal-Wallis non-parametric test, when normality assumptions were violated. The effects of age and drug, as well as their interactions, were tested. Post-hoc analyses were performed when a significant main effect was detected. An effect was considered significant at p < 0.05.

Raw data were rescaled to fit all points within the same range. Any animals with one or more data point reaching minimal or maximal detectability of the LH RIA assay were excluded based on recommendations from a biostatistician, Dr. W.Y. Wendy Lou. Thus, the numbers of animals shown in the Results section differ from the initial numbers of animals assigned to this study. The final n’s used for analysis are presented in the figure legends. The initial data point for each data set was dropped to limit effects of stress on LH levels during the initiation of serial blood sampling, and the final data point was excluded from analysis because it was collected at the time of terminal decapitation. Finally, no differences were observed in irregularly cycling middle-aged animals (n = 25) when compared to those in persistent estrus (n = 8), so these groups were combined.

GnRH mRNA Analysis. GnRH mRNA levels were normalized to the housekeeping gene cyclophilin in each animal. All results are expressed as the mean ± SEM. ANOVA was performed by the StatView 5.0 program for Macintosh computer to ascertain differences between groups. Results were considered significant at p < 0.05.

Fig. 1. Individual profiles of pulsatile LH release, measured in serum samples collected every 10 min in representative young (a, b) and middle-aged (c, d) OVX, cholesterol replaced female rats. Please note that the y-axis scales vary among treatment groups to better demonstrate individual pulses. Animals were injected with vehicle or ifenprodil (10 mg/kg) 1 h after blood sampling began. Arrows indicate the time point immediately preceding the injection. Asterisks indicate significant pulses as indicated by the Cluster pulse detection software. Chol = Cholesterol.

Results

Effects of Ifenprodil on LH Release in Young and Middle-Aged Female Rats

The LH profiles for 2 representative animals from each group of cholesterol- and 17β-E₂-treated animals are shown in figures 1 and 2 respectively. Rats had detectable pulses of LH in all treatment groups. As expected, serum LH levels were high in OVX, cholesterol-treated young and middle-aged rats (fig. 1) and were low in OVX, 17β-E₂-treated rats due to negative feedback of E₂ on GnRH and LH (fig. 2).

Cholesterol-Treated Animals. The selective NR2b antagonist, ifenprodil, had no effect on the parameters of total and pulsatile LH release, including area under the LH curve (fig. 3a), area under the peak (fig. 3b), mean LH release (fig. 3c), or LH peak amplitude (fig. 3d). In addition, in OVX, cholesterol-treated rats, none of these parameters differed between young and middle-aged rats. In this group, as well as in the E₂ animals described below, the following parameters were not significantly affected by ifenprodil: pulse frequency, pulse width, interpulse intervals, and interpeak concentrations (data not shown).

17β-E₂-Treated Animals. In contrast to the cholesterol group, there was both an age and drug effect observed for serum LH levels. Post-hoc analyses showed that middle-aged 17β-E₂-treated animals had significantly lower levels of LH as compared to young animals in the measurements of area under the LH curve (fig. 4a; p < 0.003), area under the peak (fig. 4b, p = 0.0346), mean LH (fig. 4c; p = 0.001), and peak amplitude (fig. 4d; p = 0.0039). Additionally, administration of ifenprodil caused increases in three of these parameters: area under the LH curve (fig. 4a; p = 0.0151); mean LH (fig. 4c; p = 0.014) and peak amplitude (fig. 4d; p = 0.0134), but not area under the peak.

Effects of Ifenprodil on GnRH mRNA Expression in the POA-AH of Young and Middle-Aged Female Rats

No effects of either age or hormone on GnRH mRNA levels were observed, as these were similar in cholesterol- and 17β-E₂-treated rats, as well as young and middle-aged rats (fig. 5). The only significant difference detected was for drug (ifenprodil vs. vehicle) in the middle-aged, cholesterol-treated rats. In this group, GnRH mRNA levels were modestly but significantly lower in ifenprodil-treated rats (p < 0.05) as compared to their vehicle-treated counterparts.

Discussion

The present results add to the mounting evidence for the regulation of the neuroendocrine hypothalamus by glutamate, showing for the first time a functional role for the NR2b subunit of the NMDAR. Here, we used the NR2b-selective antagonist ifenprodil and measured its effects on serum LH levels as a proxy for GnRH release, which cannot be measured in the general circulation. However, actions of NMDAR agonists/antagonists on pituitary LH release are mediated exclusively through hypothalamic GnRH neurons [1, 7, 12–14, 45, 46], and therefore, any effects of ifenprodil on LH release likely represent its effects on hypothalamic GnRH release. Our current study shows that treatment with ifenprodil results in significantly higher levels of pulsatile LH than vehicle controls. Both young and middle-aged rats were responsive to ifenprodil, and this effect was limited to rats given E₂ (but not cholesterol) treatment, suggesting that the steroid environment modifies effects of NMDAR-acting drugs on GnRH output. The implications of these findings, as discussed in greater detail below, are that the subunit composition of the NMDAR plays a role in its function in the reproductive neuroendocrine system.

17β-E₂ Levels in Young and Middle-Aged, OVX Female Rats

The average E₂ levels for OVX young and middle-aged, cholesterol-treated rats were 1.01 ± 0.14 and 0.76 ± 0.26 pg/ml, respectively. The average E₂ levels for OVX, E₂-treated young and middle-aged rats were 332 ± 102 and 314 ± 51 pg/ml, respectively. Although levels of E₂ were higher than anticipated and were often supraphysiological, each treatment group included animals with levels ranging from the physiological to the supraphysiological range, and there were no differences in results from animals across this range of E₂ levels. The results also showed comparable replacement levels of E₂ in the young and middle-aged rats.

Fig. 2. Individual profiles of pulsatile LH release, measured in serum samples collected every 10 min in representative young (a, b) and middle-aged (c, d) OVX, 17β-E₂-replaced female rats. Please note that the y-axis scales vary among treatment groups to better demonstrate individual pulses. Animals were injected with vehicle or ifenprodil (10 mg/kg) 1 h after blood sampling began. Arrows indicate the time point immediately preceding the injection. Asterisks indicate significant pulses as indicated by the Cluster pulse detection software. E₂ = 17β-Estradiol.

Previous studies have shown that at the dose used in the current study, ifenprodil is a selective antagonist for NMDARs containing the NR2b subunit [47, 48], crosses the blood-brain barrier [49, 50], and exerts actions in the central nervous system for at least 2 h [50] and up to 12 h post-application [38]. Here, ifenprodil injection enhanced pulsatile LH release in young and middle-aged OVX, E2-treated rats. This finding suggests that the presence of the NR2b subunit in NMDARs affecting GnRH neurons decreases their responsiveness to endogenous glutamate. This result may be explained by the stoichiometry and properties of the NMDAR, which is a heteromeric complex composed of an NR1 subunit, necessary for channel function, co-assembled with one or more types of NR2 (a–d) or NR3 (a, b) subunits. The subunit composition of the NMDAR alters its properties, influencing channel kinetics, intracellular responses, and ligand affinities [51]. NR1, NR2a, and NR2b are the most abundant subunits expressed in the hypothalamus [52–54] and all are co-expressed by GnRH cell bodies and nerve terminals [2, 26, 32, 55]. Of these, only the NR2b subunit shows age-associated changes, increasing its co-expression on GnRH neurons in the POA-AH, an area rich in GnRH perikarya, of middle-aged females as compared to their young counterparts [2]. A previous report indicated that the presence of the NR2b subunit in the NMDAR complex is associated with a decreased probability of channel opening, increased deactivation time, and slower recovery from desensitization when compared to NR2a [56]. Thus, it is our belief that the previously demonstrated age-related increase in NR2b co-expression on the GnRH neurons of the POA-AH, and hence an increase in the ratio of NR2b- to NR2a-containing receptors, causes delayed and decreased channel opening, resulting in a decline in the efficiency by which the NMDAR stimulates GnRH release. Our current results showing an enhancement of pulsatile LH release by ifenprodil, which selectively blocks receptors containing NR2b but would enable activity of NMDARs that do not contain NR2b, are consistent with this hypothesis.

In the present study, we observed a significant increase in area under the LH curve, mean LH, and LH pulse amplitude following ifenprodil treatment in both age groups of E2-treated OVX rats. We interpret this to mean that blockade of NMDARs containing the NR2b subunit allows other (non-NR2b-containing) NMDARs to mediate...
effects of glutamate, resulting in either an increase in the number of GnRH neurons firing or the amount of peptide being released during individual neuronal firing. This is further supported by the observed increase in mean LH and area under the LH curve. Furthermore, the lack of significant change of LH area under the peak suggests that ifenprodil is acting to increase baseline levels of LH, rather than simply increase the concentration released during each pulse.

We were surprised that OVX, E2-treated rats of both age groups responded in a similar way to ifenprodil. However, both age groups have NR2b-containing NMDARs, albeit at differing levels [2, 26, 31], and both received a treatment that altered the NMDAR population. Ifenprodil binds only to NMDARs containing the NR2b subunit, and its effectiveness at inhibiting these channels is determined by the receptor stoichiometry, specifically, the number of NR2b subunits encompassed within the channel [57]. Moreover, as discussed below, not only does ifenprodil act upon GnRH neurons, but it also exerts effects on afferents to this system that may also possess NMDARs with NR2b subunits. Thus, the heterogeneous nature of this receptor, as well as the multiple mechanisms by which it may exert influence on the reproductive axis (both directly and indirectly), suggests that ifenprodil may exert broad effects on this hypothalamic neural circuitry regulating GnRH. This may underlie why both young and middle-aged rats are responsive to ifenprodil, as it may be through different populations of NMDARs, and warrants further investigations to tease apart these mechanisms.

It seems counterintuitive that blockade of receptors for an excitatory amino acid such as glutamate may result in an up-regulation of pulsatile LH release. We feel that the most reasonable explanation is that the effects of ifenprodil are occurring not only on GnRH neurons themselves, but also on neurons that make direct and indirect inputs to GnRH cells. For example, GABA-containing neurons, the principal inhibitory neurotransmitter in the brain and the counterpart to glutamate’s role as the principal excitatory neurotransmitter, inhibit GnRH release [58, 59]. If this GABAergic inhibition is stimulated by glutamate, the removal of glutamatergic input by ifenprodil to these GABAergic neurons would disinhibit GnRH neurons, thereby facilitating GnRH release. It is even possible that the same neurons co-express glutamate and GABA and that the balance of their outputs affect GnRH release, as postulated by Ottem et al. [60]. Moreover, there are age

---

**Fig. 4.** Parameters of pulsatile LH release were determined in young and middle-aged female rats that were OVX and treated with E2. There was a significant decline with age in area under the LH concentration curve (a), area under the peak (b), mean LH (c) and LH peak amplitude (d). Ifenprodil administration resulted in a significant increase in area under the curve, mean LH, and LH peak amplitude in both young and middle-aged OVX, E2-treated rats. All data shown are mean ± SEM. n = 10, 4, 5, and 5 for young vehicle, young ifenprodil, middle-aged vehicle, and middle-aged ifenprodil, respectively. * p < 0.05 vs. comparable drug or age group; ** p < 0.01 vs. comparable drug or age group. E2 = Estradiol; VEH = vehicle; IFEN = ifenprodil; AUC = area under the curve; AUP = area under the peak.
alterations in hypothalamic-preoptic GABA release and biosynthesis in rats [61]. Thus, the balance of glutamate and GABA regulation of GnRH neurons, directly and/or indirectly, may play important roles in neuroendocrine regulation.

**E₂-NMDAR Interactions**

Ifenprodil significantly enhanced pulsatile LH release only in OVX rats treated with E₂, but not cholesterol-treated OVX rats. These findings are consistent with previous evidence for an enhanced sensitivity of the GnRH neurosecretory system to NMDAR agonists or antagonists in the presence of estrogens [13, 31, 62]. For example, pulsatile LH release in adult female OVX rats was enhanced by NMDA in E₂- but not vehicle-treated animals [13]. Similarly, MK-801, a competitive NMDAR antagonist, affected pulsatile LH release only in E₂- but not vehicle-treated sheep [62]. The site of convergence of estrogens and glutamate is still unknown, but in the case of GnRH release, it is likely to occur via inputs to the GnRH system rather than in GnRH neurons themselves [63]. Importantly, estrogen receptor-α (ERα) and NMDARs are co-expressed in cells in regions of the hypothalamus and preoptic area that regulate GnRH neurons [29], suggesting an anatomical site at which endogenous glutamate and estrogens can interact upon the same target cells to enhance the sensitivity of the GnRH system. Alternatively, or in addition, we cannot exclude the possibility that an enhanced pituitary responsiveness to GnRH in the presence of E₂ may amplify effects of ifenprodil on LH pulsatility. Taken together, this evidence suggests that NMDAR antagonists may require modulation by estrogen in order to affect pulsatile LH release, a conclusion that is consistent with the results of this study showing stimulatory effects of ifenprodil only in E₂-treated rats.

**Effects of Ifenprodil on LH Release Occur Independently of Effects on GnRH Gene Expression**

Overall, robust effects of ifenprodil on GnRH mRNA levels, an index of GnRH gene expression, were not detected. Only the middle-aged, OVX rats that were cholesterol (but not E₂) treated had decreased GnRH mRNA levels following ifenprodil compared to its vehicle control. This change, while significant, was not large in magnitude, and it is notable that this same group of rats did not respond to ifenprodil with a significant change in pulsatile LH release. This finding, together with our observations that ifenprodil significantly increases pulsatile LH release in the E₂-treated young and middle-aged rats, suggests an uncoupling of GnRH biosynthesis and GnRH release. Therefore, the majority of the effects of ifenprodil probably occur on the secretory pool of GnRH vesicles that stimulate LH pulses from the pituitary gland, without causing changes in GnRH biosynthesis, at least at the time points measured. There are several alternative or complementary explanations. It is possible that changes in GnRH mRNA may occur more rapidly (e.g., within 15 min to 1 h), similar to what has been reported for effects of N-methyl-D,L-aspartate [42, 64], whereas in the current study, rats were euthanized 4 h after ifenprodil injection. Alternatively, GnRH mRNA may replenish pools of the GnRH peptides over a longer time course. Future
studies evaluating the time course of effects of ifenprodil on GnRH gene expression will enable us to detect whether this is a target for effects of NR2b antagonism. The concept that NMDAR agonists and antagonists may exert differential effects on GnRH cell bodies (as manifested by changes in gene expression) and on GnRH nerve terminals as manifested by GnRH release is one that we have posited previously [65] and is consistent with reports that not only do GnRH cell bodies co-express NMDAR subunits [2], but that GnRH nerve terminals express NMDAR subunits [55, 66, 67] and may be a direct site of regulation by glutamate, independent of activity on GnRH perikarya.

Previous studies have shown that administration of NMDAR agonists stimulates GnRH gene expression, and that this effect is dependent upon reproductive status, age, sex, hormonal status, and the time points observed following administration [42, 68, 69]. There is much less information as to the effect of NMDAR antagonists on GnRH gene expression. Seong et al. [70] reported that administration of the NMDAR antagonist MK-801 to OVX, estrogen- and progesterone-treated adult female rats caused a decrease in GnRH gene expression in hypothalamic fragments. Ottem et al. [69] found that while estrogen induced an increase in GnRH gene expression in lateral and medial POA, MK-801 was not effective in inhibiting this increase. Our results showed no effect of ifenprodil on GnRH gene expression in E2-treated OVX rats of either age, and a small but significant decrease in GnRH mRNA levels only in middle-aged OVX rats, in the absence of E2. These data reinforce previous work showing that the sensitivity of this system, depending upon time of day, estrous cycle status, and/or hormonal environments, together determine GnRH gene expression.

Conclusions

This study provides further evidence that the subunit composition of the NMDAR, and specifically the NR2b subunit, contributes to the regulation of GnRH/LH release in the female hypothalamus. Blockade of NMDAR-NR2b in the presence of E2 has a stimulatory effect on GnRH neurons, resulting in increased pulsatile LH output. Although pulsatile release of LH was similarly affected by ifenprodil in the two age groups, GnRH mRNA expression was selectively decreased only in one group, the cholesterol-treated middle-aged rats. These results suggest a dissociation of effects of glutamate, acting through NMDA receptors containing the NR2b subunit, on pulsatile GnRH release and GnRH gene expression.

Acknowledgments

This work was supported by the Glenn/American Federation for Aging Research (AFAR) scholarship for research in the biology of aging to J.A.M., and NIH PO1 AG16765 and RO1 AG028051 to A.C.G. We wish to thank Dr. Wendy Lou for statistical analysis of pulsatile LH release. Thanks also to Brittany Makos for excellent technical assistance in all areas of this study. We are grateful to Dr. A.F. Parlow of the National Hormone and Pituitary Program at NIDDK for providing LH assay reagents.
