Hemimasticatory spasm (HMS) is an infrequent condition that consists of involuntary sustained unilateral contractions of masticatory muscles. After the first description by Gowers in 1897 as 'masticatory spasm' [1], at least 19 additional cases of HMS have been reported (table 1) [2–17], some of them associated with facial hemiatrophy [2, 3, 6, 7, 9, 11–13].

The characteristic electromyographic (EMG) findings of HMS are irregular bursts of motor unit potentials lasting from seconds to minutes, which correlate clinically with the involuntary twitches or spasms of the masticatory muscles [4, 10, 13]. Involuntary spasms are selectively confined to the masseter, temporalis and, occasionally, medial pterygoid muscles.

The pathophysiology of HMS is not well known. Some authors suggested a close similarity with hemifacial spasm [2, 5] and proposed that the spontaneous activity was generated in the trigeminal nerve fibers [2, 4]. On the other hand, other authors suggested the central nervous system, sympathetic ganglia or muscle dysfunction [3, 7]. Some reports support the trigeminal nerve dysfunction hypothesis, by which ectopic activity of motor fibers of the trigeminal nerve should cause decreased motor nerve conduction of the

affected nerve, increased latency or absence of the masticatory reflex and absence of the silent period of the masseter reflex during spasms [10, 13, 14, 17].

We report a patient who showed a typical HMS of 4.5 years of evolution, which had developed 6 months after a biopercular syndrome.

Case Report

A 45-year-old male patient was evaluated because of involuntary spasms in his right masseter muscle. Five years before, following an acute respiratory insufficiency which required endotracheal intubation, he had presented with dysarthria, bilateral (predominantly right) supranuclear facial and hypoglossal palsy, and inability to achieve tongue protrusion, difficulty in chewing and bilateral dystonia of the hands. At that time, the case of this patient was published because of the presence of bilateral asymmetrical hand dystonia associated with bilateral opercular lesions (Foix-Marie-Chavany syndrome) [18]; he did not have HMS and was lost to follow-up. Six months after the first admission to hospital (4.5 years before the new evaluation), he developed a progressive clinical picture of sustained involun-

tary contractions of the right masticatory muscles. Needle electromyography of the right temporal and masseter muscles showed no abnormal spontaneous activity during the resting state, and the activation and recruitment patterns of motor units were normal. However, during periods of involuntary spasms, the right temporalis and masseter muscles showed bursts of motor potential units at high frequencies. Needle electromyography of the left temporalis and masseter muscles showed no abnormalities. Blink reflexes, obtained by electrical stimulation of the supraorbital nerve on each side, were of normal latency and symmetrical on both the unaffected and affected sides. Masseter inhibitory reflexes, evoked by electrical stimulation of the mental nerves, showed normal values of the latencies and duration of the silent periods SP1 (monosynaptic) and SP2 (multisynaptic) on both the unaffected and affected sides. T₂- and FLAIR-weighted images in brain MRI showed hyperintense lesions in both parietal opercula (fig. 1a–c), and a ⁹⁹Tc-HMPAO SPECT showed reduced captation of the tracer in both parietal regions (fig. 2). The patient received local injection of botulinum toxin type A (Botox), 30 IU in the right masseter and temporalis muscles, with slight improvement, and was again lost to follow-up.

Discussion

The patient reported here showed typical clinical and EMG findings of HMS. However, he presented with 3 interesting features: (a) the latencies of the masseter inhibitory reflex were normal; (b) the clinical course of the HMS was progressive and started 6 months after an acute hypoxic-ischemic insult which caused biopercular lesions, and (c) previously, this patient

had developed acute bilateral hand dystonia.

Mastication is achieved by cooperation between facial, masticatory and lingual muscles [19]. According to anatomical findings and functional animal studies, the orofacial area is related with both hemispheres. Studies performed with rabbits have shown that after bilateral cortical masticatory area (CMA) ablation, the animal cannot manipulate food placed in the

front of the mouth for several days, with a following partial recovery [20], while repetitive stimulation of the CMA (which has projections to the ventral region of the putamen) elicits rhythmic jaw movements [21, 22]. While cats with unilateral lesion of the CMA showed no changes in mastication except for prolongation of the food intake and masticatory periods, cats with bilateral CMA lesions showed wide jaw opening during mastication, delay in the

start of mastication, abnormal tongue protrusion and difficulty in manipulating food on the tongue [23, 24].

Kempainen et al. [25] performed a study in patients with unilateral cortical infarction in the region of the middle cere-

bral artery and showed no impairment of masticatory force and function. On the other hand, Cruccu et al. [26] studied the masseter inhibitory reflex in 15 patients with hemiplegia and found normal latencies of both SP1 and SP2 components of

this reflex, but reduced amplitude and increased habituation of the SP2 evoked by stimulation of the paretic side. These authors concluded that, though the masticatory nucleus receives bilateral innervation, the contralateral hemisphere should exert

a predominant control of voluntary activity and multisynaptic reflexes.

HMS is usually considered to be related with peripheral affection of the trigeminal nerve [2, 4, 10, 13, 14, 17]. This is supported by the presence of delayed jaw jerk [6, 10, 14, 16] and the absence of silent periods of the masseter inhibitory reflexes [9, 12, 13, 14, 17, 26] or 'efferent block' [26]. In patients with trigeminal neuropathy, both SP1 and SP2 components of the masseter inhibitory reflexes should be delayed or reduced in size, while a lesion to the masticatory nucleus or motor axons can cause an ipsilateral muscle weakness and a reduction in the voluntary EMG activity, but the reflex inhibition should remain evident [27].

Recently, Frontera and Pallesstrany [28] have reported a patient who developed acute trismus associated with biopercular syndrome due to stroke. A possible explanation of the fact that our patient developed a unilateral masticatory syndrome with a bilateral opercular lesion should be the asymmetry of these lesions (shown in fig. 1). Although there is no clear explanation for the delayed appearance of this syndrome, it could be speculated that it is due to the interruption of the corticopontine pathways, as it is was described with acute pseudobulbar or suprabulbar palsies, some of them related with opercular infarcts [29]. The present report raises the possibility that HMS could also be associated with bilateral asymmetrical cortical lesions like those presented by our patient with a previous biopercular syndrome. These data suggest the possible role of some cortical areas of the human brain in the control of mastication, as it has been reported in some experimental models.
