Key Words

Hypoxia, renal parenchymal • Chronic kidney disease •
Oxygenation, renal tissue

Abstract

Renal parenchymal hypoxia, documented under a variety of clinical conditions, conceivably contributes to the progression chronic kidney disease. In this review, normal physiologic medullary hypoxia and abnormal profiles of renal pO_2 in chronic kidney diseases are presented, and the mechanisms leading to anomalous renal tissue oxygenation are discussed. Direct measurements of pO_2 with oxygen electrodes, immunostaining with pimonidazole (which binds to regions with very low pO_2), or the detection of hypoxia-inducible factor (HIF)- α (which accumulates in hypoxic regions, initiating hypoxia-adaptive responses), all serve to detect the distribution and extent of renal parenchymal hypoxia under experimental settings. The use of BOLD MRI as a noninvasive tool, detecting deoxygenated hemoglobin in hypoxic renal tissues, has evolved from experimental settings to human studies. All these modalities indicate that abnormal renal oxygenation develops under conditions such as chronic glomerular, tubulointerstitial or renovascular disease, in diabetes, hypertension, aging, renal hypertrophy, anemia or obstructive uropathy. Abnormal renal tissue

hypoxia modifies the pattern of regional gene expression, evoking a host of adaptive and renoprotective pathways (such as HIF-mediated erythropoietin or heme-oxygenase-1), in parallel with the induction of potentially harmful mediators that participate in the progression of chronic kidney injury. Slowing the progression of chronic kidney disease may be achieved by a better understanding of these parallel processes and the accomplishment of a selective control of such protective and maladaptive responses.

Introduction

Kidney function, determined as the glomerular filtration rate (GFR), declines at a rate of about 1 ml/min per year. In patients with chronic kidney disease (CKD), the rate of decline in GFR is accelerated and may reach over 10 ml/min per year.

This review, presented in part at the International Society of Nephrology meeting, Rio de Janeiro, 2007, was supported by a grant from Russell Berrie Foundation and D-Cure, Diabetes Care in Israel, and by the Harvard Medical Faculty Physicians at Beth Israel Deaconess Medical Center, Boston, Mass., USA.

Fig. 1. Renal medullary oxygen balance. The renal medulla normally functions under hypoxic conditions, reflecting limited oxygen supply, barely sufficient for intense regional oxygen consumption for tubular transport. Low oxygen delivery results from limited blood supply and oxygen diffusion from descending to ascending vasa recta (illustrated in inset). Regional oxygen consumption is governed by factors affecting the extent of solute delivery for distal tubular reabsorption, as well as to the control of transport activity. VR = Vasa recta; GFR = glomerular filtration rate; PT = proximal tubules.

Color version available online

In the 1980s, Brenner et al. [1, 2] suggested that altered glomerular hemodynamics govern the accelerated progression of chronic renal failure (CRF). They assumed that an initial reduction in renal cell mass leads to a ‘wear and tear’ phenomenon, with glomerular hypertension, hyperfiltration, and hypertrophy of functioning glomeruli, ultimately ending with glomerular sclerosis, glomerular dropout, and the generation of an ongoing vicious circle of progressive renal damage.

The major flaw in this hypothesis is that in patients with chronic renal disease the extent of renal dysfunction poorly associates with changes in glomerular morphology, whereas it correlates well with chronic tubulointerstitial injury [3]. This has shifted the interest to multiple other factors, including proteinuria and associated interstitial cytokine release, in the progression of CKD [4]. Numerous studies have underlined the importance of oxygen free radicals, vasoactive substances, tubular hypertrophy, hypermetabolism, and endothelial dysfunction, but noteworthy, until 1998 the word ‘hypoxia’ was still missing in graphic illustrations of this complex pathophysiology [5].

In 2000, Fine et al. [6] pointed out that inhibitors of the renin-angiotensin-aldosterone axis slow the progression of CRF regardless of the control of hypertension or the presence or absence of proteinuria. Their review forms the basis for a new evolving concept on the role of hypoxia in the progression of CKD. They proposed that kidney injury leads to a vicious circle of tissue fibrosis, pursuant obliteration of the renal microvasculature, hypoxia and continued damage [6].

Indeed, renal parenchymal hypoxia has been consistently documented by currently available technologies. Regional renal microcirculation and PO₂ can be continu-

ously monitored under experimental settings with needle-laser Doppler flow probes and with oxygen microelectrodes, respectively. The distribution of renal parenchymal hypoxia and hypoxia adaptive responses can now be mapped using immunostaining for pimonidazole (molecular ‘hypoxia probe’ which, following injection, binds to tissues with oxygen tension below 10 mm Hg) and for hypoxia-inducible factors (HIF; see below). Finally, blood oxygenation level-dependent (BOLD) MRI provides a noninvasive measure to determine the dynamic changes in the distribution and extent of deoxygenated hemoglobin within the renal parenchyma. Based on these technologies, we shall appraise the evidence for renal parenchymal hypoxia under conditions that predispose to accelerated progression of CKD, providing insight into potential interventional measures in efforts to retard the decline in kidney function.

Renal Oxygen Profile: The Nature of Renal Medullary Hypoxia

Renal parenchymal oxygenation reflects the balance between regional oxygen supply and oxygen consumption, principally for tubular transport [7, 8]. Oxygen demand is governed by GFR, by tubular and ion-pump mass, and by various regulators that control transport activity. Oxygen supply mirrors systemic and intrarenal factors that control intrarenal blood flow and distribution, the oxygen-carrying capacity of the blood, and the specific structure of the renal microcirculation. Peritubular capillaries are nourished by efferent glomerular arterioles. Efferent arteriolar PO₂ is lower than renal venous PO₂, implying cortical precapillary shunting that

Fig. 2. The control of renal medullary oxygen balance. Medullary oxygen sufficiency is maintained by matching regional oxygen supply and demand. Tight control of these factors is maintained by various mediators, including nitric oxide (NO), prostaglandins (mainly PGE₂) and adenosine, which increase medullary blood flow and downregulate tubular transport. Importantly, suppression of GFR, in part through moderate cortical vasoconstriction, reduces solute delivery for distal tubular reabsorption and subsequent oxygen consumption. Some of these control systems are hampered in CKD, for instance single-nephron GFR is increased, or regional NO and PGE₂ synthesis are faulted. Reactive oxygen species (ROS) also interfere in this delicate balance, by causing endothelial dysfunction and through dis-inhibition of tubular transport.

leads to renal parenchymal hypoxia [9]. Furthermore, a non-homogenous distribution of renal parenchymal oxygenation exists, with renal parenchymal pO₂ sharply declining at the cortico-medullary junction, reaching levels as low as 25 mm Hg within the renal medulla under normal physiologic conditions [7, 10]. This physiologic hypoxia of the renal medulla stems from limited oxygen supply, barely sufficient for ample regional oxygen consumption (fig. 1). The medulla receives some 10%, only, of total renal blood flow originating from efferent arterioles of deep juxtamedullary glomeruli. These blood vessels merge to form vascular bundles (vasa recta), a central component of the renal concentrating machinery. Importantly, the unique architecture of a countercurrent blood flow in vasa recta facilitates oxygen diffusion from descending to ascending blood vessels and contributes to reduced oxygen availability to the medulla. At the same time, the outer medullary oxygen requirement for tubular transport by medullary thick ascending limbs (mTALs) and S3 (straight) segments of the proximal tubules is intense. Complex mechanisms participate in the preservation of renal medullary oxygen sufficiency, by the control and matching of both intrarenal blood flow and tubular transport activity (fig. 2). Prostaglandins (principally PGE₂), nitric oxide, adenosine and other mediators act in concert to maintain this oxygenation balance by enhancement of medullary blood flow and sup-

pression of tubular transport. Reduction of GFR is one of the mechanisms that maintain medullary oxygenation by reducing solute delivery for reabsorption in the distal nephron. It is noteworthy that reactive oxygen species (ROS) undermine these protective mechanisms, compromising ambient microcirculation and counteracting mechanisms that attenuate tubular transport [7, 8, 10].

Changes in medullary oxygenation following the administration of non-steroidal anti-inflammatory agents illustrate the importance of the protective mechanisms mentioned above: regional medullary blood flow (determined by laser Doppler probes) acutely declines and tubular transport is enhanced, leading to a substantial fall in ambient oxygenation over a protracted period of time [11, 12]. Evidently, chronically intensified medullary hypoxia underlies the pathophysiology of analgesic nephropathy, characterized by medullary fibrosis and papillary necrosis.

Renal HIF during Hypoxic Stress

Chronic tissue hypoxia invokes a hypoxic response, mediated to large extent by HIFs [10, 13–15]. These ubiquitous key transcription factors consist of α - and β -subunits. The α -subunit is rapidly degraded and removed under normal ambient oxygenation by specific oxygen-

sensitive prolyl hydroxylases. Hypoxia inactivates the degradation of HIF- α by these enzymes, and it accumulates and binds with the β -subunit. The formed heterodimer translocates into the nucleus, binds to hypoxia-response elements and activates a host of HIF-mediated genes that participate in cell adaptation to hypoxia. There are over 100 genes known to be mediated by HIF, which control cell metabolism and survival, angiogenesis, vascular tone, and tissue oxygenation. Heme oxygenase-1, erythropoietin, and VEGF are among the long list of HIF-mediated cytoprotective genes.

There are at least two HIF- α isoforms. Renal HIF is cell-type specific with HIF-1 α isoform principally expressed in tubular segments (mostly in collecting ducts), while HIF-2 α is detected in vascular endothelial and interstitial cells. Genes expressed by HIF are also cell- and locus-specific, for instance, erythropoietin is selectively induced by interstitial cells at the cortico-medullary junction [16]. Not surprisingly, this region, functioning on the verge of hypoxia, serves in the control of the blood oxygen-carrying capacity.

Using immunostaining for both pimonidazole and HIF, as well as for the expression of HIF-mediated genes, we have recently mapped the extent and distribution of renal hypoxia under acute settings, such as global renal hypoxia or intrarenal regional vascular obliteration, following the administration of non-steroidal anti-inflammatory or radiocontrast agents, during the induction of hypoxic acute renal failure or following rhabdomyolysis [17–20]. With these methods applied at different intervals after insults we could detect the spatial and chronological evolution and recovery of localized intrarenal critical hypoxia, and the pursuant induction of the HIF-mediated hypoxic response.

Mechanisms for Intensified Renal Hypoxia in CKD

CKD is characterized by intensified renal hypoxia. Using BOLD MRI, Manotham et al. [21] noticed the enhanced concentration of deoxygenated hemoglobin within the medulla (i.e. intensified regional hypoxia) in humans with CKD as compared with control healthy kidneys. Interestingly, medullary hypoxia has been attenuated following the administration of an angiotensin II (AII) receptor antagonist. These observations illustrate that AII plays an important role in the generation of renal hypoxia in CKD [22]. BOLD MRI may also identify whole-kidney or segmental renovascular disease affecting parenchymal oxygenation. Importantly, in these set-

tings BOLD MRI may distinguish between severely compromised but viable parenchyma (high basal values of deoxygenated hemoglobin, falling after the administration of furosemide) and non-functional scar tissue (low basal levels, unaffected by furosemide) [23].

Basile et al. [24] showed that chronic tubulointerstitial disease also leads to depletion of peritubular capillaries, illustrated by microfil infusion into rat kidneys 4–8 weeks after ischemia/reperfusion injury. In this model the capillary volume and perfusion index fall in all renal regions along time, meaning less oxygen supply. Furthermore, evolving fibrosis and the deposition of extracellular matrix interferes with ambient oxygen diffusion [24]. As the peritubular capillaries originate from efferent glomerular arterioles, it is noteworthy that primary glomerular diseases with obliteration of glomerular capillaries also compromise downstream peritubular microcirculation and intensify parenchymal hypoxia [25, 26].

Nephron depletion per se may intensify renal hypoxia: uninephrectomy results in the expression of pimonidazole adducts in the remaining kidney, evidence of intense hypoxia, conceivably reflecting hypertrophy, enhanced GFR and increased tubular transport [27]. Similarly, pimonidazole immunostaining is more pronounced following uninephrectomy in a model of experimental nephritis, characterized by peritubular capillary depletion, fibrosis, and inflammation [25].

In an experimental model of chronic tubulointerstitial disease induced by ischemia-reflow injury, regions with depleted renal microvasculature and expanded extracellular matrix display deposition of pimonidazole, indicating critical hypoxia, as well as HIF expression, reflecting a cellular response to hypoxia [28]. Similar indices of evolving hypoxia were noted in other animal models of hypoxic/nephrotoxic tubulointerstitial disease induced by adriamycin, cyclosporine A and folic acid [29–31]. Both pimonidazole and HIF immunostaining are more pronounced in kidneys with moderate tubulointerstitial changes, as compared with severely damaged kidneys [28]. Possibly this has to do with a more pronounced reduction in GFR in the more injured kidneys, with subsequent lower oxygen consumption for tubular transport. Thus, the distorted anatomy of CKD can augment hypoxia, but with extreme loss of functional tissue this hypoxic condition may diminish.

Aging is also associated with intensified renal hypoxia. As shown by BOLD MRI, ambient pO_2 is some 20 mm Hg lower both in the cortex and the medulla in otherwise healthy aged individuals, as compared with tracings undertaken in young subjects [32]. Hypoxia and hypoxia

adaptation were also noted in aged rat kidneys, using immunostaining for pimonidazole, HIF and HIF-mediated genes [33]. This may reflect the reduced capacity of the aged kidney to generate nitric oxide and PGE₂ [34–36].

Diabetes also predisposes to renal parenchymal hypoxia, as shown by Palm et al. [37] using oxygen microelectrodes in rats. The decline in parenchymal oxygenation in the diabetic kidney is most pronounced in the medulla, and principally reflects enhanced tubular transport. Renal oxygenation in the diabetic kidney is restored by the administration of antioxidants, which scavenge ROS and normalize transport activity. Medullary hypoxia in the diabetic rat kidney has also been documented using BOLD MRI [38, 39] and with pimonidazole and HIF immunostaining [40]. These indices of medullary hypoxia disappear with the control of hyperglycemia. Interestingly, though hypoxia is ameliorated [37], HIF expression intensifies with the addition of a ROS scavenger [40], suggesting that ROS suppresses hypoxic adaptive responses. These findings are in agreement with studies in cultured proximal tubular cells and in diabetic rats, showing oxidative stress-regulated attenuation of the HIF-VEGF pathway [41].

Thus, the role of hypoxia in the progression of injury in the diabetic kidney is now well acknowledged [42] to be induced by oxidative stress and ROS, by altered renal hemodynamics (in part through altered nitrovasodilation [43]), inflammation and fibrosis. Hypoxia may also be enhanced by increased GFR, tubular hypertrophy and transport activity.

Hypertension may also lead to renal hypoxia, as determined with oxygen microelectrodes in hypertensive rats [9]. Intensified hypoxia in these animals reflects enhanced oxygen demand due to defective coupling of tubular transport and oxygen consumption. As with diabetes, ROS is considered to contribute to reduced renal blood flow and to an inefficient use of oxygen for sodium transport [44].

Chronic salt and volume depletion may invert the normal renal oxygenation gradient: under such experimental conditions cortical pO₂ declines, representing decreased total renal blood flow and vasoconstrictive stimuli, whereas medullary oxygenation paradoxically improves [45]. The attenuated medullary hypoxia conceivably reflects decreased tubular transport due to reduced GFR, enhanced proximal tubular reabsorption, mTAL atrophy and cortico-medullary redistribution of renal blood flow.

Hypoxia may also exist in transplanted kidneys, as shown by HIF immunostaining in human renal trans-

Table 1. Postulated mechanisms responsible for declining renal oxygenation in CKD

<i>Decreased oxygen supply</i>
Peritubular capillary loss
Interstitial fibrosis
Glomerular sclerosis and a decline in downstream peritubular flow
Anemia
Altered vascular tone
Decreased nitric oxide and prostaglandin synthesis
Enhanced vasoconstrictive stimuli: AII-induced efferent arteriolar vasoconstriction; enhanced endothelin-1
Oxidative stress
<i>Increased oxygen consumption</i>
Tubular hypertrophy and enhanced GFR in remnant nephrons
Repeated transiently enhanced GFR (high-protein meals)
Oxidative stress-related dis-inhibition of tubular transport

plants, especially during cellular rejection [46]. However, BOLD MRI studies disclosed contradictory findings, where medullary physiologic hypoxia was attenuated in rejected kidneys [47]. Differences in the magnitude of GFR decline and subsequent attenuation of transport activity might explain these discrepancies.

Low hematocrit also results in decreased oxygen supply to the kidney. As shown with oxygen microelectrodes inserted into the kidney during acute decrements in hematocrit, both cortical and medullary pO₂ decline [48]. Renal parenchymal HIF accumulation appears under comparable conditions, such as exposure of the animal to carbon monoxide [17].

BOLD MRI experimental studies indicate that urinary outflow obstruction results in reduced cortical oxygenation, while medullary pO₂ increases [49]. Conceivably, this reflects a renovascular response to obstruction, with reduced cortical blood flow and GFR, with a subsequent reduced distal tubular transport activity.

Finally, renal hypoxia in CKD may hypothetically reflect additional causes for enhanced oxygen consumption: ineffective proximal tubular work could shift reabsorption to more distal tubular sites where ATP and oxygen costs may be higher. Additional metabolic workload and oxygen consumption might be related to gluconeogenesis, to reabsorption and degradation of excessively filtered proteins or to chemical utilization of oxygen via activation of various kidney oxidases. The quantitative contribution of such putative mechanisms in the evolution of renal hypoxia in CKD remains speculative.

Table 2. Studies [reference numbers] giving evidence of renal hypoxia in CKD and in conditions predisposing to CKD

Clinical setup	Study type		BOLD MRI	Oxygen electrodes	Immunostaining

Thus, to summarize, renal ‘physiologic’ hypoxia that normally exists at certain regions is aggravated in a host of clinical conditions that predispose to the evolution of chronic kidney disease. The mechanisms that reduce renal oxygenation in CKD are summarized in table 1 (modified from Nangaku [50]). Table 2 illustrates existing evidence for renal parenchymal hypoxia under a variety of clinical and experimental conditions of CKD.

Renal Hypoxia Response: Bad and Good Components

Renal hypoxia leads both to desired and undesired effects that in most cases perpetuate the progression of CKD through an ongoing vicious circle. As shown in figure 3, the two main initiating factors are hypoxia and ROS, induced during hypoxia. These initiating proceedings trigger transcription factors, HIF and non-HIF, and a host of effectors classified as harmful or protective mediators with regard to the general outcome from the renal perspective. Their action culminates in a list of subsequent physiopathologic processes that participate in the progression of CKD. Among the harmful effectors are the renin-angiotensin-aldosterone axis, endothelin, plasmin-activator inhibitor-I, adhesion molecules and growth factors which, triggered by hypoxia, induce endothelial dysfunction, vasoconstriction, microvascular depletion, inflammation, fibrosis and tubular and glomerular dam-

age. These effects perpetuate the vicious circle of ongoing hypoxia and progressive renal damage.

Against them rise hypoxia-triggered protective effectors, many of them HIF-dependent, such as erythropoietin and vascular endothelial growth factor (VEGF), which somewhat counteract the effect of the harmful pathways, promoting angiogenesis, improving tissue oxygenation and cell survival, and facilitating homing of progenitor cells [51]. Indeed, rats with chronic tubulointerstitial disease [28] or diabetes [40, 52] have shown unexpected resistance to acute hypoxic insults, conceivably through hypoxia tolerance, induced by HIF-mediated pathways. However, it is noteworthy that diabetic kidneys subjected to extreme hypoxic conditions, such as warm ischemia-reflow [53] or ex vivo perfusion with red cell-free perfusate [52], are highly vulnerable to hypoxic damage, suggesting that HIF-mediated reno-protection is ineffective beyond a ‘window of opportunity’ of *moderate* acute hypoxic stress [54].

The gross distinction between the harmful and protective effectors is not always easily done. It may depend to large extent upon the intensity and persistency of their expression and on the concomitant action of other mediators. Some may have dual actions: for instance nitric oxide synthase isoforms mediate vasodilation, but also lead to the formation of peroxynitrite. Even VEGF, generally considered renoprotective, may after all not be fully so, as evidenced by a human genotype characterized by enhanced VEGF expression, associated with a higher rate of end-

Fig. 3. Schematic presentation of hypoxia-driven renal parenchymal destructive processes and their related mediators. Key regulation of these processes may occur through HIF and non-HIF mechanisms, such as p53 or STAT3. Effectors can roughly be divided into protective and destructive mediators, and to some with both potentially injurious and protective characteristics. This is a simplistic and partial scheme only, and evidence for the association of hypoxia and reactive oxygen species (ROS) and these individual effectors and pathophysiology is often incomplete or speculative.

stage renal disease [55]. The complex associations of the various effectors with kidney hypoxia have recently been detailed in depth by Norman and Fine [51].

In the perspective of the compound structure of the kidney and its vasculature, evaluating the precise location of an upregulated system is highly important. For instance, hyperglycemia/hypoxia-related induction of endothelin precursors and their regulator, endothelin-converting enzyme-1, is associated with the induction of endothelin-ET_B receptors in the vasa recta and peritubular capillaries [56]. It is noteworthy that ET_B receptors mediate endothelin-induced vasodilatation [57]. Thus, induction of a most potent vasoconstrictor is coupled with localized activation of a counterbalancing system that maintains medullary oxygenation.

Therapeutic Implications

Interventions that were found to attenuate progressive CKD evidently may relieve renal parenchymal hypoxia. The importance of blocking the renin-angiotensin system is underscored by improved medullary oxygenation following the administration of AII receptor blockade [21]. Indeed, the renal protective effects of these agents lie far beyond the mere correction of hypertension and the attenuation of proteinuria [58, 59]. The correction of anemia is of utmost importance in the attenuation of the progression of CKD, and so is the control of glucose levels in the prevention of progressive diabetic nephropathy. Plausibly, a low salt and protein diet attenuates enhanced GFR and transport activity in the remaining nephrons and may prevent subsequent tissue hypoxia. The potential benefit of selective manipulation of hypoxia renoprotective adaptive responses has also been suggested. Indeed, intrinsic HIF upregulation in experimental CKD and in the diabetic kidney seemingly confers protection against acute hypoxic insults [28, 40], and the individual impact of exogenous erythropoietin, one of the major renoprotective HIF-target genes, in delaying the progression of CKD has been suggested in experimental and clinical settings, probably regardless of the correction of anemia [60, 61]. It is tempting to assume that upstream enhancement of HIF by specific inhibitors of prolyl hydroxylases may attenuate the progression of CKD [50, 51], as it seemingly reduces kidney injury in acute settings [62]. However, caution is warranted since such an intervention on a chronic basis might activate undesired genes as well.

In conclusion, renal hypoxia does occur throughout the progression of CKD as has been shown by a variety of methods; it is multi-factorial and conceivably plays a role in CKD progression. The kidney responds to declining ambient oxygenation by the activation of genes providing adaptation and endurance, as well as with the induction of pathways with a potential destructive nature. Through the later responses, a vicious circle develops with enhanced fibrosis and microvascular depletion, and subsequent hypoxia and progressive kidney damage.

The significance of the mechanisms of renal hypoxia and hypoxic response in the diseased kidney should be further elucidated by interventional studies. This may help us in the development of therapeutic interventions, intensifying protective mechanisms and eliminating maladaptive responses.
