Allogeneic bone marrow transplantation is the only proven cure for chronic myeloid leukaemia (CML). The timing of bone marrow transplantation in individual patients can be difficult although clinical variables may provide some guide to urgency [1]. The oncogenic events underlying the Philadelphia chromosome are now well described and molecular variations may also have prognostic significance. Several groups have suggested that the position of the bcr breakpoint may influence the chronic phase duration; however, these findings have not been confirmed by other authors [reviewed in ref. 2]. One variable hindering comparison of these studies has been the different methods used to examine the bcr breakpoint position. Using the methods of Mills et al. [3], and probes kindly provided by these authors, the bcr breakpoint position was determined in 40 patients with CML. Table 1 compares patients with 5' and 3' bcr breakpoints. The chronic phase duration was not significantly different between the two groups ($p = 0.122$). The distribution of breakpoints by zone was similar to that previously described [2]. These findings do not confirm the conclusions of Mills et al. [3] that the chronic phase duration in CML is shorter in pa-

tients with 3' bcr breakpoints. This is despite the fact that we have used identical methods and probes as these authors. We agree that patient variables may explain the different conclusions of these studies and that a long-term prospective study may be required to resolve this controversy. Included in this study is a patient with an exceptionally long chronic phase (20 years); molecular analysis revealed a zone 5 (3') breakpoint. Such patients suggest that oncogenic events unrelated to bcr-abl are involved in the progression of CML.
