Yawning · Migraine · Stroke · Tic

Abstract
Yawning is a physiological behavior, an emotional stereotopy that indicates the homeostatic process of the mechanisms regulating rhythms, such as sleeping/waking, hunger/satiety or mating/relaxation, generated by the diencephalon. As with all physiological behaviors, its deregulation reveals disorders. In daily practice, yawning as a symptom is generally neglected. That is why we propose a wide overview of yawning in diseases, its consequences and significance.

Yawning is a phylogenetically old, stereotyped phenomena that occurs in reptiles, fish, birds and mammals. A yawn is a paroxystic cycle characterized by a standard cascade of movements over a 5- to 10-second period. The mouth, previously closed, opens widely for 4 to 6 seconds with simultaneous retraction of the tongue, and is usually combined with retroflexion of the head and sometimes elevation of the arms (pandiculation). This movement pattern is often repetitive. Yawning clearly appears to be not just a matter of opening one’s mouth, but a generalized stretching of the muscles of the respiratory tract (diaphragm, intercostal), face and neck. Thus, it can be inferred that yawning is a part of the generalized stretch with which it is generally accompanied [1, 2].

Yawning and pandiculation are associated with transitions between wakefulness and sleep, occurring at the onset of hunger or satiety and with the ebb and flow of emotional states secondary to living in hierarchical social groups [3]. They exteriorize the activity of the motor centers of the brainstem (V, VII, IX, X, XI, XII) and of the spinal cord under the control of the hypothalamic paraventricular nucleus (PVN). The PVN is a point of integration between the central and peripheral autonomic systems. Among other things, it plays a role in metabolic balance (osmolarity, energy), blood pressure and heart rate, and sexuality. Yawning and pandiculation can be triggered by injections (apomorphine, hypocretins, etc.) or inhibited after an electrical lesion in the parvocellular zone of the PVN. A group of oxytocin neurons situated in this zone and projecting to the hippocampus, the brainstem (locus ceruleus) and the spinal cord control yawning and erection. The stimulation of these neurons by dopamine or its agonists, such as excitatory amino acids (NMDA), histamine and oxytocin itself, triggers yawning and erection, whereas GABA and opioids have an inhibitory effect [4, 5]. A specific role for the dopamine D3 receptor in this behavior has yet to be elucidated. Collins et al. [6] report that dopamine D2/D3 agonists elicit dose-dependent yawning behavior in rats, resulting in an inverted U-shaped dose-response curve. The induction of yawning is a D3 receptor-mediated effect, whereas the inhibition of the yawning observed at higher doses is due to competing D2 receptor activity [6].

As with all physiological behaviors, its deregulation reveals disorders that we now present.

Can one talk about the ‘disease of yawning’? H. Meige and G. Feindel [7, p. 346] wrote in 1902 in their famous book, Tics and their Treatment (Les tics et leur traitement):
Yawning and sneezing, which, like swallowing, are reflexive phenomena whose mechanism is voluntarily modified only with great difficulty, can hardly be perturbed except with respect to their frequency. Saenger (Observations on the idiopathic spasm of the tongue, Monatsschrift für Psychiatrie und Neurologie, January 1900, p. 77) reported on the case of a 29-year-old woman, who was not hysterical and who presented with episodes of yawning with rigidity in the arms, followed by rapid contractions of the tongue for around a minute. She recovered after several months. The case concerned an ‘idiopathic spasm’, probably some sort of tic. However, these functional anomalies of yawning or sneezing most often occur in hysterical subjects. It should also be remembered that yawning may be the aura of an epileptic seizure. Uncontrollable yawning is also seen in meningitic incidents, and in cases of tumors of the brain or cerebellum.

The analysis of clinical observations in light of neurophysiological knowledge accumulated over a century allows us to affirm the existence of pathological yawning and to distinguish between its various forms: the dissatisfaction of incomplete yawning, the disappearance of yawning and the excess of repeated yawning.

**Anhedonia**

Frustration due to an incomplete or inharmonious development of a yawn is a frequent complaint. Yawning is a stretching of respiratory muscles and muscles of the face, and is sometimes associated with a generalized muscular stretching of the trunk and limbs. The yawner perceives differences in muscle tonus, a veritable and conscious extraction of the progress of the phenomenon, its stimulus and contextual valence, through interoceptive pathways (projections by the lateral spinothalamic tract onto the insular cortex) leading to a hedonic perception. The dissatisfaction felt seems to be linked to an unconscious inhibition of the ‘letting go’ that underlies a complete yawn. Therapeutic interventions for anxiety states or for insomnia, such as relaxation or sophrology, use the control of yawning as a means of relaxation or an antistress aid, a veritable proprioceptive rehabilitation of the body scheme [8, 9].

**The Disappearance of Yawning**

Yawning is a banal action, often barely noticed or felt. It seems that its disappearance is not perceived. Complaints of missing the feeling of well-being associated with yawning, due to the absence of yawning, remain the exception. In daily life, there appears to be no particular consequences of not yawning. The reality of this fact can be questioned, since some yawns could occur without being felt or noticed. Certain extrapyramidal syndromes are accompanied by a disappearance of yawning, such as in the case of treatment with neuroleptics [10] or Parkinson’s disease [11]. This disappearance indicates the activity state of the dopaminergic neurons of the PVN of the hypothalamus, which are necessary for yawning. Experimental pharmacology has shown the specificity of the D3 dopamine receptors in triggering this behavior [12]. While the neuroleptics currently in use have no specific target of action, one may assume that the presence or absence of yawning in Parkinson’s disease reflects the state of the neuronal population (functional or undergoing degenerative involution). The treatment of episodes of motor blocks in Parkinson’s patients by apomorphine hydrochloride, a rapid-action dopaminergic stimulant, triggers yawning, as does treatment with L-DOPA, but in a less systematic fashion [13–15]. Dewey et al. [16] notes this effect in 8% of the patients treated, and its absence in the case of a placebo injection. Yawning is clearly described by the patients not as discomfort, but as a signal of unblocking, and indicates the beginning of the effect of the relieving treatment [17–20].

**Excessive Yawning**

The most common cause of frequent and repeated yawning is sleep debt, particularly in children and young adults. Campaigns for the prevention of falling asleep while driving emphasize this warning sign of the risk of falling asleep involuntarily. Research on accident prevention is leading to the development of programs for the automatic detection of yawning and blinking by the driver in order to trigger an alarm that forces the driver to stop [21]. Drowsiness can be assessed by establishing an Epworth Score, in order to uncover a syndrome of sleep apnea or other cause of hypersomnia. In children, drowsiness is often manifested by excessive agitation, punctuated by yawning, with an attention-fixing deficit. Before invoking the diagnosis of a possibly hyperactive child, it is advisable to eliminate any sleep apnea syndrome caused by an obstructive hypertrophy of the tonsils or adenoids. Evans [22] describes, in the same spirit, 2 cases of inhalation of foreign bodies into the bronchi, which manifested as suffocation alternating with yawning in succession.

Dyspepsia, or the sensation of a full stomach and slow digestion, and an irritable colon are often associated with salvos of yawns. Considering the importance of the autonomic nervous system, particularly the parasympathetic...
system, in the regulation of digestive functions, it is not surprising that yawning appears to be associated with problems that are essentially functional. The term 'gut brain' or digestive neurology has been used in this context in order to avoid restricting the pathophysiology of this system to motor deficits and to also take into account the sensitivity of the digestive system (visceroception, a component of interoception) [23, 24]. The discovery of hypocretin, a neuromediator that triggers sensations of hunger and arousal, could also provide an explanation [25]. It is possible that leptin, the messenger of satiety, and ghrelin, another messenger signaling hunger, play roles that have not yet been elucidated [26]. These functional digestive disorders should be seen in light of a vasovagal episode. The circumstances under which it is triggered are multiple: violent emotion, intense pain, the sight of blood, staying in a confined and overheated space, etc. The most common form of the malaise, a loss of consciousness, which occurs in subjects of all ages regardless of their state of health, is preceded by a rich parade of premonitory disorders that attest to a hyperstimulation of the parasympathetic system: pallor, nausea, salvos of yawning, visual disturbances, etc. The appearance of yawning is a sign that should attract the attention of a health-care worker during invasive exploration and allow him/her to anticipate a loss of consciousness and subsequent fall. Dorsal decubitus, or an injection of atropine, eliminates the malaise and yawning [27]. Motion sickness, or kinetosis, is a related functional disorder that is often accompanied by repetitive yawning before the onset of vomiting [28]. The beginning of hypoglycemia in a diabetic under insulin therapy is accompanied by a feeling of hunger, profuse sweating and repeated yawning, similar to the feeling of hunger in nondiabetics.

With a progression that is often insidious, an increase in the frequency of yawning becomes embarrassing both because of the brief pause in activity that it causes and because of the negative social connotations perceived by both the yawner and his/her entourage. Often occurring in salvos of 10–20 successive yawns, the daily number of visits to pharmacovigilance agencies and there are neither statistics to assess the frequency of this iatrogenic effect, nor any studies showing that it is revealed by association with another psychotropic drug [38]. Curiously, while tricyclic antidepressants have atropinic side effects, thus being inhibitors of yawning, and are reputed to lead to impotence, there have been reports regarding excessively frequent salvos of yawning that accompany involuntary orgasms with clomipramine [39, 40].

Concerning dopamine agonists, we have already discussed the injection of apomorphine hydrochloride during episodes of motor block in Parkinson’s patients in order to restore motricity. It is not possible to invoke a real iatrogenic effect here. Apomorphine hydrochloride, at lower doses administered orally, is used to treat male impotence. Data sheets accompanying the product indicate yawning as a rarely reported side effect seen during the initial clinical studies. Since commercialization, no follow-up data have been accessible. Data for other dopaminergic agonists (bromocriptine, lisuride, pergolide, ropinirole, pramipexole, selegiline and piribedil) are no doubt lacking as a result of faulty pharmacovigilance, since animal models show evidence of the same iatrogenic risks [41, 42].

Detoxication after prolonged use in heavy users of coffee or of opiates is accompanied by the withdrawal syndrome of repetitive yawning over several days [43–49]. The clinical profile of a neonate with a mother who consumes opiates, legal (methadone, morphine) or not until the end of her pregnancy, can be impressive with respira-
Migraines are one of the most common disorders in humans, affecting 10–20% of the population at least once a year. It appears to be secondary to a combination of environmental and genetic factors. Clinical and pharmacological findings, as well as recent developments in genetics, confirm the hypothesis that a dysfunction in dopaminergic transmission plays a role in the pathophysiology of a migraine attack. Prodromes (changes in mood, yawning, somnolence, food aversion, etc.) may be related to dopaminergic overstimulation. The dopaminergic system also plays a role in the headache phase on the one hand by participating in nociceptive pathways, and on the other by intervening in the regulation of cerebral arterial circulation. Apomorphine induces more yawning in migraineurs than in nonmigraineurs [14, 52–54]. The shimmering blind-spot is a classic sign of a visual aura. However, a large number of migraineurs have noted that repeated yawning in salvos also acts as an aura before an attack [55–57]. More rarely, the attack ends with repeated yawning, accompanied by drowsiness and a postdrome profile [58, 59].

Yawning can be studied from several angles during the course of a stroke. During the occurrence of an attack, ischemic or hemorrhagic, deficits in vigilance occur accompanied by salvos of yawning, whether or not the victim is conscious [60–62]. This could be due to intracranial hypertension consequent to the stroke. In the case of a deep coma (Glasgow Score = 3), the occurrence of repetitive yawning is a sign of herniation – a grave prognostic sign. Apart from this extremely serious evolution, yawning during the course of a stroke indicates damage to the cortical and subcortical circuitry, and to a mechanism of secondary vigilance stimulation controlled by the reticular formation of the brainstem, a mechanism probably common to the yawning that occurs during a partial seizure in temporal lobe epilepsy. During an ischemic attack affecting the territory of the lenticulostriate arteries, damage to the internal capsule and/or the lentiform nucleus leads to complete hemiplegia due to the lesioning of the pyramidal tracts, while the extrapyramidal pathways are spared. In this case, the paralyzed arm can be seen to move during yawning, bringing the hand up to the mouth. The arm drops immediately following the end of the yawn. We have named this syndrome, which is not a synkinesis, ‘parakinesia brachialis oscitans’. With regard to its phylogeny, it has been shown that in quadrupeds like the dog and the horse, there is a synchronization of the ventilatory rhythm with that of gait: 1 ventilatory cycle per gait cycle, with concomitant acceleration while running. In humans, bipedalism has led to the loss of this automatic synchronization, retaining only the swing of the arms while walking, but no strict synchrony with ventilation. After a stroke has interrupted cortical control, the subjacent neurological structures retrieve their ancestral functions, which are normally inhibited by the overlying cerebral structures as a result of evolution. During the movement of the diaphragm while yawning, the paralyzed arm receives motor stimulation from the lateral reticular nucleus of the medulla which couples ventilation and locomotion in animals, an extrapyramidal signal that is not inhibited by the ischemic lesion. In 2 stroke profiles, the persistence of yawning and emotional facial expressions signals the dissociation between automatic and voluntary pathways. In the case of a ‘locked-in’ syndrome caused by an occlusion in the basilar artery territory, there is quadriplegia in association with bilateral facial paralysis. However, physiological yawning continues to occur [63–65]. Similarly, in bilateral anterior opercular syndrome, or Foix-Chavany-Marie syndrome, the muscles of the face, tongue and laryngopharynx are paralyzed during all voluntary acts, including voluntary smiles or grimaces, as well as during language articulation, whereas the expression of emotions, eye blinking, laughing, coughing, swallowing and yawning remain possible. No voluntary imitation of these movements can be carried out. The cause is ischemic, or more rarely post-traumatic, damage to the frontoparietal opercular areas bilaterally [66, 67].

Intracranial hypertension, whether related to a stroke, tumor [68–70] or head trauma [71], can be revealed by headaches and by disturbed vigilance associated with salvos of yawns and convulsions. Certain coma scores used in the USA take into account the presence of yawning in these situations [72, 73]. Vegetative states of postischemic lesion, or from other origins, also display ‘automatic-voluntary dissociation’ with the persistence of frequent yawning [74].

Charcot presented a patient in 1888, referred to above, and reported by Gilles de la Tourette in 1890 [75] as suffering from hysteria. Nevertheless, this young woman of 23 years was amenorrheic, epileptic, suffered from a bimaxillary loss of the visual field and yawned 480 times an hour. In reality, she was probably developing a prolactinoma of the hypophysis. I have also personally observed a 39-year-old acromegalic male with prognathism and moderately protruding brows, suffering from persistent asthenia with salvos of almost 200 yawns per day (unpublished). Similarly, Wong et al. [70] reports a case of a mu-
cocele of the sphenoid sinus compressing the pituitary stalk, which was revealed by the occurrence of yawning repeated every 15 seconds. There are a number of clinical arguments to show that an unexplained excess of yawning could be the result of a hypothalamic-pituitary disorder, the mechanism of action of which could be the over-secretion or inappropriate release of oxytocin or other neuromediators due to compression [76, 77].

There has been little interest in the behavioral disturbances that precede or succeed an epileptic seizure by a few minutes or several hours. Nonetheless, these anomalies could provide orienting data that help to localize the anatomical origin of focal seizures. Before, as well as after, a temporal, or sometimes frontal, epileptic seizure, different automatismas such as rubbing the nose with the fingers, yawning or sighing can be observed. As Jackson wrote around 1876 [78]: ‘These symptoms do not occur during but after the paroxysm of the seizure; these are movements that are too well coordinated to result from an epileptic discharge; there exists, I think, a double condition: (1) negatively, a loss of control; (2) positively, an augmentation of the activity of the inferior functional center. In any case, the association or the sequence of gestures is very significant’. In accordance with behavioral data, there is a phylogenetic origin to these stereotypical behaviors. They are noticeable during the fetal stage, and continue into the postnatal period and throughout life. Scratching the face, rubbing the nose, yawning and sighing have been described as automatic behaviors that occur before or after absence seizures or focal seizures. They can also be seen in healthy subjects as they awake from sleep. They can be distinguished as being physiological, at waking, or pathological, for example in temporal lobe epilepsy, depending on whether their velocity is harmonious or not, and whether their repetition is brief or prolonged. These behavioral automatismas are related to the activation of the brainstem or the spinal cord, the seat of their motor and integrative centers. The cortex, where the seizure is localized, is not involved. Thus we see the reappearance of ancestral behavioral automatismas that are necessary for survival (such as walking, swimming, mating and other rhythmic activities, to which yawning also belongs) by a liberating ictal cortical disconnection [79–83]. Goldie and Green [84] present 3 observations found from old reports of Gowers (1885) [85], Penfield and Jasper (1954) [86] and Symonds (1950) [87] of children suffering from ‘petit mal’ seizures, the beginnings of which are signaled by repeated yawning. In addition to the association between temporal lobe epilepsy and yawning, Penfield and Jasper [86] describe di-

encephalic epilepsy, a rare type of epilepsy, whose existence has been questioned by some epileptologists. It brings together the brutal stimulation of sympathetic and parasympathetic activity: a feeling of disconnection from the environment without loss of consciousness; a ‘vaso-motor storm’ with flush; profuse sweating; a rapid rise and fall of body temperature, pulse and arterial pressure; lacrimation; salivation; pupillary inequality; and irregularities of the ventilator rhythm. Salvos of yawning and irrepressible hiccupping accompany this spectacular and very unpleasant profile. The cases described reveal the presence of thalamic tumors [88–92]. D’Mello et al. [93] also report salvos of yawns as an iatrogenic effect of the withdrawal of neuroleptics, persisting several months after convulsions are provoked. They propose a lesioning of the hypothalamus by way of explanation.

Occurring at the threshold between absence seizures and epilepsy of a psychogenic origin, prolonged hyper-ventilation (voluntary or unconsciously induced), can alter the level of consciousness, mimicking an epileptic fit, with the appearance of automatic movements such as smiling, swallowing or yawning [94, 95]. Positive or negative emotions are accompanied physiologically by modifications in cardiorespiratory activity, mediated by the autonomic nervous system. Thus, an increase in the frequency of ventilation is one of the signs of a panic attack. The hyperventilation syndrome comprises a neurotic profile on its own, leading to respiratory alkalosis, accompanied in more than 30% of cases by repeated widely spaced yawns that could be seen as a homeostatic counterstimulation of the parasympathetic system [96–100]. The use of relaxation techniques and yoga designed to trigger relaxing yawns allows these problems to be treated [101].

In 2006, in a study published exclusively on the internet, Galazzaro [102], of Holyoke Community College (Holyoke, Mass., USA), demonstrated the existence of a link between the frequency of yawning reported by depressive patients and severity of the depression, using a small sample of 31 patients. Depression was evaluated with the help of the Goldberg Scale, and yawning was evaluated on the basis of a questionnaire proposed by Greco and Baenninger [103]. Statistical analysis of the results demonstrated a significant link: the more the patient yawned, the more severe the depressive state was. This was the first time that such a study was performed. To the surprise of the author, there was a negative correlation between age and yawning. It should be noted that the number of yawns produced diminishes physiologi-
cally with age, and that the predictive value of the relation between yawning and depression is probably lost after 65 years. It should also be remembered that antidepressants, in particular serotonergic antidepressants, promote repeated yawning.

At present, it is quite rare to encounter a schizophrenic who does not take neuroleptics, which, by their mode of action, inhibit yawning. In the past, the reappearance of yawning in a schizophrenic was interpreted as a resumption of contact with the environment and socialization [104]. Salvos of yawns, such as seen in at least 3 of the 5 cases reported by Gilles de la Tourette in 1890, could have a psychogenic cause as a form of nonverbal language. They have been described as an urgent and irresistible feeling following a sensation of epigastric heaviness with ascendant retrosternal constriction, relieved by undergoing a ventilatory period of yawning that yields brief pleasure such as that described by patients affected by nervous tics [105, 106].

Sandyk [107] has reported a series of 5 patients in the initial stages of Steele-Richardson-Olszewski syndrome, or progressive supranuclear palsy, with balance deficits, oculomotor problems and salvos of repeated yawning that were reduced, paradoxically, by the administration of dopaminergic agonists. Louwerse (1998) [108] reports the existence of excessive yawning in salvos in around 10% of 200 patients with the bulbar form of amyotrophic lateral sclerosis, or Charcot’s disease, which is also the case in the study carried out by Williams [108]. Wicks [109] sees this problem in 47% of patients in a series of 539. Present during the initial phase of the disease, concurrently with the appearance of swallowing deficits, yawning disappears with the aggravation of paralysis. A brainstem attack in multiple sclerosis can yield the same profile [110].

Between 1917 and 1925, an epidemic of encephalitis, described as lethargic by von Economo [111] (1876–1931), invaded all of Europe. After an initial meningitic phase, a lethargic phase lasting several weeks set in. These acute symptoms, often mortal, were succeeded in those who survived by a ‘chaos of abnormal movements’ (Pierre Marie), with the combinations of depressive or delirious manifestations, oculogyric crises, Parkinsonian syndromes, etc. In 1921, Sicard and Paraff [112] reported observations in which the initial lethargic phase was followed by spasmodic attacks of hiccupping, laughing or crying, and salvos of repetitive yawning several times a day. The homogeneity of the process of morbidity and the relative consistency of the lesion sites were in contrast to the polymorphism of the clinical manifestations. Contemporary discoveries confirm the soundness of the hypotheses put forward by von Economo. Autoimmune injury to the basal ganglia of the hypothalamus leads to a rarefaction of orexin/hypocretin-containing neurons, among others, and decreases, either transiently or permanently, the secretion of certain neuromediators responsible for arousal.

At the end of this vast panorama, the consultation of a patient complaining of excessive yawning can be schematized. The first step consists of looking for an iatrogenic effect, the most frequent cause. Then, a search for abnormal drowsiness or sleep debt should allow any syndrome of sleep apnea to be uncovered. Functional causes leading to an anxiety disorder, possibly associated with a hyperventilation syndrome, should be treated by relaxation and yoga. This should be correlated with the occurrence of dyspepsia. Clinical examination is needed to detect pituitary/hypophyseal endocrine anomalies, intracranial hypertensive syndromes, a partial temporal seizure, stroke or Charcot’s disease. Finally, repeated yawning could form part of a tic disease.
