Abstract

Background/Aims: In cerebral arteries, nitric oxide (NO) release plays a key role in suppressing vasomotion. Our aim was to establish the pathways affected by NO in rat middle cerebral arteries. Methods: In isolated segments of artery, isometric tension and simultaneous measurements of either smooth muscle membrane potential or intracellular \([\text{Ca}^{2+}]\) changes were recorded. Results: In the absence of L-NAME, asynchronous propagating \([\text{Ca}^{2+}]\) waves were recorded that were sensitive to block with ryanodine, but not nifedipine. L-NAME stimulated pronounced vasomotion and synchronous \([\text{Ca}^{2+}]\) oscillations with close temporal coupling between membrane potential, tone and \([\text{Ca}^{2+}]_{\text{SMC}}\). If nifedipine was applied together with L-NAME, \([\text{Ca}^{2+}]_{\text{SMC}}\) decreased and synchronous \([\text{Ca}^{2+}]\) oscillations were lost, but asynchronous propagating \([\text{Ca}^{2+}]\) waves persisted. Vasomotion was similarly evoked by either iberiotoxin, or by ryanodine, and to a lesser extent by ODQ. Exogenous application of NONOate stimulated endothelium-independent hyperpolarization and relaxation of either L-NAME-induced or spontaneous arterial tone. NO-evoked hyperpolarization involved activation of BK\textsubscript{Ca} channels via ryanodine receptors (RYRs), with little involvement of sGC. Further, in whole cell mode, NO inhibited current through L-type voltage-gated \([\text{Ca}^{2+}]\) channels (VGCC), which was independent of both voltage and sGC. Conclusion: NO exerts sGC-independent actions at RYRs and at VGCC, both of which normally suppress cerebral artery myogenic tone.

Introduction

Cerebral arteries typically display spontaneous, submaximal constriction that is dependent on the level of intraluminal pressure or isometric stretch, termed myogenic tone. This myogenic tone is an essential mechanism in the local control of blood flow and tissue perfusion in the cerebral vasculature both in vivo and in vitro, and in many other vascular beds [1, 2]. The development of myogenic tone is generally characterized by vascular smooth muscle cell depolarization, leading to an increase in intracellular \([\text{Ca}^{2+}]\) and associated constriction of the artery [1, 3]. Myogenic responses, by definition, can occur without a functional endothelial cell layer; how-
ever, the endothelium can considerably modulate the degree of myogenic tone by releasing a number of factors including nitric oxide (NO), prostacyclin and endothelium-derived hyperpolarizing factor.

In addition to suppressing myogenic tone, endothelium-derived factors also modulate the vasomotion that often occurs in tandem with the development of myogenic constriction. Vasomotion describes rhythmic oscillations in tension or diameter that are normally synchronous with oscillations in Ca\(^{2+}\) and membrane potential (E\(_m\)). In the brain, oscillations in middle cerebral artery blood flow velocity (as a result of vasomotion) have been observed in many species, including humans [4] and rats [5]. The role of the endothelium in the control of vasomotion is unclear; in some vascular beds the NO/cGMP pathway has been shown to augment vasomotion [6]. However, in other beds, including the cerebral vasculature [5, 7], NO/cGMP attenuates this response as NO synthase (NOS) inhibitors stimulate vasomotion. This vasomotion manifests as a reduction in capillary blood flow, which tends to oscillate in synchrony within the bed [8]. Therefore, any disruption of the ability to synthesize NO can potentially lead to vasomotion and/or spasm, as observed under pathophysiological conditions such as subarachnoid haemorrhage [9, 10].

In arteries isolated from both coronary [11, 12] and cerebral [13–20] beds, a continual, basal release of NO suppresses myogenic tone, with inhibition of NOS leading to depolarization and constriction in the absence of vasoconstrictor agents. NO can either stimulate hyperpolarization and closure of voltage-gated Ca\(^{2+}\) channels (VGCC), or directly close VGCC, both of which suppress myogenic tone. In terms of hyperpolarization, NO can activate smooth muscle cell BK\(_{Ca}\) channels either directly [21–23] or via PKG-dependent mechanisms [24, 25]. NO can also stimulate ryanodine-sensitive calcium stores (by opening the ryanodine receptor, RYR) in the sarcoplasmic reticulum, evoking discrete calcium events termed ‘sparks’ that activate adjacent clusters of BK\(_{Ca}\) channels. This mechanism has been suggested to underpin NO-dependent relaxation in the rat posterior cerebral artery [26] where the presence of NO is reported to be a prerequisite to activate the RYRs. Stimulation of RYRs by NO could be either direct or indirect, such as nitrosylation of thiol groups [27], or via cGMP-mediated phosphorylation of the channel and the sarcoplasmic reticulum calcium ATPase [28], respectively. In addition, NO can close VGCC in a membrane potential-independent manner, which can occur either via sGC/PKG [29–31] and/or by nitrosylation [32–34].

Therefore, we investigated further the mechanisms underlying the modulation of myogenic tone and the development of vasomotion associated with the basal release of NO in the rat (middle) cerebral arteries. Although our data support the suggestion that NO does stimulate RYR channels to release calcium that drives BK\(_{Ca}\) channel-mediated hyperpolarization, they also suggest 2 further important aspects of NO activity. First, that inhibition of NOS masks (rather than inhibits) spontaneous oscillations in smooth muscle cell calcium due to activation of VGCCs and the appearance of vasomotion, which is consistent with activation of RYRs via NO-independent pathways. Second, a direct inhibitory action of NO on VGCCs can suppress cerebral artery myogenic tone.

Materials and Methods

Male Wistar rats (200–300 g) were euthanized using procedures defined by the Animals (Scientific Procedures) Act 1986, UK (schedule 1 procedure) and the brain was rapidly removed and stored immediately in ice-cold physiological salt solution for a maximum of 30 min.

Simultaneous Measurement of Tension and Membrane Potential

A 2-mm segment of the middle cerebral artery (internal diameter of approx. 175 \(\mu\)m) was mounted in a Mulvany–Halpern myograph (model 410A; Danish Myotechnology) in Krebs solution containing (in mM): NaCl, 118.0; NaCO\(_3\), 25; KCl, 3.6; MgSO\(_4\), 1.2; KH\(_2\)PO\(_4\), 1.2; glucose, 11.0; CaCl\(_2\), 2.5; and gassed with 95% O\(_2\) and 5% CO\(_2\) at 37 °C. The vessels were allowed to equilibrate for 20 min and were then tensioned to 1–1.5 mN (approximates wall tension at 60 mm Hg). Vessel viability was assessed by the addition of exogenous K\(^{+}\) (15–55 mM), only vessels developing tension \(\geq 3\) mN were used. Endothelial cell viability was assessed by the ability of SLIGRL (20 \(\mu\)M; a protease-activated receptor 2 ligand) to relax U46619-induced tone by \(>70\)% and to hyperpolarize the smooth muscle cell membrane by \(>15\) mV. All blocking drugs were allowed to equilibrate for 20 min before study except nifedipine and ryanodine which produced immediate responses or whose effects were studied over a 20-min period. In some experiments, endothelial cells were removed by gently rubbing the luminal surface with a human hair; subsequent relaxation of \(<15\)% to SLIGRL (20 \(\mu\)M) was considered as successful removal. Smooth muscle cell tension and E\(_m\) were measured simultaneously as previously described [35] and were recorded with the use of Powerlab system (AD Instruments). Briefly, individual smooth cells were impaled with a glass electrode (filled with 2 M KCl, tip resistance 60–100 M\(\Omega\)) held perpendicular to the cells.

Simultaneous Measurement of Changes in [Ca\(^{2+}\)]\(_{SMC}\) and Tension

A segment of middle cerebral artery was mounted as described above except in a Mulvany-Halpern myograph designed for use on a confocal microscope (model 120CW; Danish Myotechnology) and in MOPS buffer containing (in mM): NaCl, 145; KCl, 4.7;
CaCl$_2$, 2.0; MgSO$_4$, 1.17; MOPS, 2.0; NaH$_2$PO$_4$, 1.2; glucose, 5.0; pyruvate, 2.0; EDTA, 0.02; NaOH, 2.75 (the pH of the solution was adjusted to 7.39–7.41 at 37°C using NaOH or HCl, as appropriate). The arteries were loaded with the calcium-sensitive fluorescent dye Oregon Green 488 BAPTA-1 AM (10 μM; dissolved in DMSO and 0.02% (w/v) Pluronic-F-127) for 1 h. After excitation at 488 nm, the fluorescence emission intensity at 515 nm was recorded using a spinning disc confocal microscope (Yokogawa CSU22) fitted with an Andor iXON DV887ES-CV camera mounted on an Olympus IX70 inverted microscope using a water immersion objective (×40, aperture 0.8, working distance 3.3 mm; Olympus) and images (512 × 512 pixels, 20 Hz) were stored for offline analysis (iQ; Andor). Following background subtraction, average relative changes in [Ca$^{2+}$]$_{SMC}$ were calculated as changes in intensity of fluorescence divided by fluorescence at time 0 s (F/F$_0$), within selected cell regions (5 × 5 pixels).

Isolated Smooth Muscle Cell Patch Clamp Experiments

Freshly dissected middle cerebral arteries were placed in ice-cold Ca$^{2+}$-free isolation solution containing (in mM): NaCl, 140; KCl, 4.7; MgCl$_2$, 1.2; glucose, 10; HEPES, 10 (pH 7.4). After incubation on ice for 20 min, the arteries were transferred to Ca$^{2+}$-free isolation solution, containing 1 mg/ml papain (Sigma) and 1 mg/ml dithiothreitol, and allowed to digest for 20 min at 37°C. The tissue was then transferred into a solution containing 0.1 mM CaCl$_2$ and 1 mg/ml collagenase type H (Roche) plus 1 mg/ml collagenase type F (Sigma). Following digestion for 10 min at 37°C, the tissue was washed in isolation solution containing 1 mg/ml albumin and 0.1 mM CaCl$_2$. After gentle trituration, cells were centrifuged for 5 min at 1,000 rpm, the supernatant removed, and resuspended in fresh isolation solution. The concentration of extracellular calcium was increased over the next 30 min to 750 μM. Freshly isolated cells were maintained on ice for use on the same day.

Cells were placed in a heated recording chamber (RC-25F; Warner Instruments) and left for approximately 10 min to adhere to the cover glass. Cells were then continually superfused (approx. 1 ml/min) with heated solution (SH-27B Inline Heater; Warner Instruments) via a multi-barrel gravity-fed perfusion system. Experiments were performed using an agar bridge (2% agar filled with 3 M KCl). During seal formation, cells were superfused with physiological saline solution containing (in mM): NaCl, 140; KCl, 4; CaCl$_2$, 1.5; MgCl$_2$, 1.2; HEPES, 10; glucose, 10; pH 7.4. To record membrane potential, the pipette solution contained (in mM): KCl, 130; NaCl, 10; HEPES, 10; MgCl$_2$, 0.5; CaCl$_2$, 0.5; Ampthoterin B (200 μg/ml). To record L-type calcium current (I$_{CaL}$), the whole cell mode was used and Ba$^{2+}$ was used as the charge carrier. Cells were perfused with solution containing (in mM): NaCl, 120; CsCl, 4; TEA-Cl, 10; BaCl$_2$, 10; MgCl$_2$, 1.2; HEPES, 10; glucose; pH 7.4. The pipette solution contained (in mM): CsCl, 130; MgCl$_2$, 0.4; HEPES, 10; EGTA 2; CaCl$_2$, 0.4; GTP, 0.5; MgATP, 5; pH 7.3. The osmolarity of all solutions was measured and corrected to 300 ± 5 mOsm using mannitol. All electrophysiological recordings were performed at 37°C.

I$_{CaL}$ was recorded using a 1-second ramp protocol, from –100 to +80 mV from a holding potential of 100 mV at a frequency of 0.05 Hz. Nifedipine (1 μM) was applied at the end of the protocol and subtracted from the current records obtained in barium-containing solution, and the data presented as nifedipine-sensitive current. Cell membrane capacitance was measured using a 10-mV hyperpolarizing step and used to correct I$_{CaL}$ currents for cell size. Currents were expressed as current density (pA/pF). Any cell exhibiting current rundown in control conditions was excluded from the analysis. NONOate was freshly diluted with physiological saline solution, and infused via an injection port in the superfusion line directly upstream from the recording chamber. In experiments with the sGC inhibitor 1H-(1,2,4)oxadiazolo(4,3-a)-quinoxalin-1-one (ODQ), cells were incubated in 10 μM ODQ for 15 min, and it was also included in the perfusion solutions. Data were analyzed and leak subtracted offline using pClamp 8 (Axon Instruments). Values are expressed as means ± SEM of n cells (from at least 3 animals). The non-paired t test was used to compare parameters obtained in control and test conditions in the same cell. A non-paired t test was used to compare the differences between groups of data.

**Solutions and Drugs**

Exogenous K$^+$ was added as an isotonic solution, and expressed as the final bath concentration. Caffeine, N$^6$-nitro-L-arginine methyl ester (L-NAME), nifedipine, ryanaidine, BayK 8644 and papaverine were all obtained from Sigma. Iberiotoxin (IbTx) was obtained from Latoxan; DEA-NONOate from Alexis; ODQ from Tocris; SLIGRL from Auspep; Oregon Green 488 BAPTA-AM from Molecular Probes; TRAM-34 was a gift from Dr. H. Wulff (University of California, Davis, Calif., USA); U46619 was obtained from Calbiochem. All drugs were made in 0.9% NaCl except ryanaidine, nifedipine, ODQ, U46619 and Amphotericin B in DMSO; NONOate in 0.01 M NaOH (and stored at ~80°C), and (~) BayK 8644 in EtOH. All subsequent dilutions of all drugs were made in 0.9% NaCl and vehicle had no effect. NONOate dilutions were kept on ice in the dark and were discarded after 20 min.

**Statistical Analysis**

Results are expressed as the mean ± SEM of n animals. Relaxation is expressed as the peak percentage reduction of the total vascular tone (from the myogenic tone to the tension/diameter following addition of papaverine, 150 μM) or as mN, as appropriate. Constriction is expressed in mN or as a percentage of maximal constriction induced by exogenous K$^+$ (55 mN), as appropriate; all values were the peak values. When oscillations in membrane potential or tension were observed, values are the average of 10 s. Graphs were drawn and statistical comparisons made using either Student’s t test or one-way ANOVA with Tukey’s or Dunnett’s post hoc test using Prism software (Graphpad).

**Results**

**Effect of Inhibiting NOS, sGC, RYRs and BK$_{Ca}$ Channels on Myogenic Tone**

Rat middle cerebral arteries exhibit myogenic tone in a wire myograph equivalent to approximately 15% of the maximum tension the vessel can develop [18], and associated with a resting membrane potential (E$_{m}$) of –50 ± 0.2 mV (n = 9). Addition of the NOS inhibitor L-NAME (100 μM) evoked depolarization (to E$_{m}$ –43.7 ± 1.9 mV, n = 6) and constriction (increase in tension of 3.7 ± 0.5 mN,
n = 7; fig. 1). In addition, oscillations in E_m developed, temporally linked to oscillations in tension (fig. 1; table 1). Fluorescence imaging revealed that in unstimulated control arteries, smooth muscle cells displayed spontaneous and asynchronous propagating Ca^{2+} waves (172 of 210 cells; fig. 1; online supplementary video 1, www.karger.com/doi/10.1159/000235964). The oscillations occurred with a frequency of 0.27 ± 0.02 Hz (n = 21; table 1) and were not associated with any change in tension (fig. 1). Addition of L-NAME increased the global [Ca^{2+}]_{SMC} (data not shown) associated with the development of synchronous Ca^{2+} oscillations between smooth muscle cells that clearly linked temporally to changes in tension (fig. 1; online supplementary video 2; table 1).

The BK_{Ca} channel inhibitor IbTx (100 nM) and the sGC inhibitor ODQ (10 μM) both mimicked this effect of L-NAME. Each caused depolarization (to E_m –40.3 ± 1.8 mV, n = 5 and n = 3, respectively; fig. 2) and vasoconstriction (increases in tension of 3.7 ± 0.8 and 3.8 ± 0.7 mN, n = 6 and n = 3, respectively; fig. 2) associated with the development of oscillations in E_m temporally linked to oscillations in tone (table 1). Note that the vasomotion induced by ODQ was at a significantly lower frequency than that with either IbT or L-NAME (table 1).

Inhibition of RYRs with ryanodine (10 μM) also mimicked the effect of L-NAME causing depolarization (13.5 ± 3.6 mV) and tension increases (2.3 ± 0.2 mN, n = 5), and associated development of synchronous E_m oscillations temporally linked with tension oscillations (fig. 3; table 1). Similarly, ryanodine stimulated synchronous Ca^{2+} oscillations in phase with tension changes (fig. 3; table 1).

Effect of L-NAME and Ryanodine on Oscillations in [Ca^{2+}]_{SMC} in the Presence of Nifedipine

As ryanodine and L-NAME each evoke constrictor responses associated with depolarization (and consequent calcium entry via VGCC) the effects of these drugs were assessed in the presence of the L-type VGCC inhibitor, nifedipine (1 μM). Under control conditions, nifedipine alone hyperpolarized (6.4 ± 2.4 mV) and relaxed (0.76 ± 0.03 mN) myogenic tone (n = 4), associated with a slight but significant reduction in both the frequency (0.20 ± 0.02 Hz, n = 4, p < 0.01) and the number of cells

Data are expressed as means ± SEM (n = 4–11). Time-matched, paired values were obtained from simultaneous records of either E_m and tension or Ca^{2+} and tension. ND = Not determined. * p < 0.05 significant difference from L-NAME.
exhibiting asynchronous propagating Ca\(^{2+}\) waves (to 70%, 28 of 40 cells; fig. 4). Subsequent addition of L-NAME repolarized the smooth muscle E\(_m\) (depolarization of 7.5 \(\pm\) 3.8 mV, \(n = 4\)) and caused a small increase in tension (0.8 \(\pm\) 0.01 mN, \(n = 4\)), returning E\(_m\) and tension values close to values recorded in quiescent vessels.

In the presence of nifedipine, L-NAME had no significant effect on the number of cells exhibiting asynchronous propagating Ca\(^{2+}\) waves (68%, 27 of 40 cells) or the wave frequency (0.22 \(\pm\) 0.02 Hz, \(n = 4\); fig. 4). In contrast, ryanodine completely abolished these Ca\(^{2+}\) waves (to 0 in 60 cells; fig. 4).
Effect of Blocking VGCC and Application of Exogenous NO or Caffeine on \textit{L}-NAME-Induced Tone

In vessels pre-constricted with \textit{L}-NAME, nifedipine (1 \textmu M) abolished oscillations in \(E_m\) and caused a repolarization (hyperpolarization of 11.7 \pm 1.9 mV, \(n = 3\)) to circa –50 mV, the resting membrane potential in the absence of NOS inhibition. This was associated with complete reversal of \textit{L}-NAME-induced tone (93.1 \pm 1.6\%, \(n = 3\)). Furthermore, nifedipine caused a large decrease in [Ca\textsuperscript{2+}]_{SMC} (data not shown) and abolished the synchronous Ca\textsuperscript{2+} oscillations between SMC, unmasking the asynchronous propagating Ca\textsuperscript{2+} waves (compare fig. 4b to fig. 1b).

In vessels pre-constricted with \textit{L}-NAME, application of caffeine (30 \textmu M to 3 mM) induced concentration-dependent hyperpolarization (log \(EC_{50}\): –3.29 \pm 0.16, \(n = 4–9\); 3 mM: 18.9 \pm 5.5 mV, \(n = 4\)) and relaxation (log \(EC_{50}\): –3.43 \pm 0.10, \(n = 7–8\); 3 mM: 91.8 \pm 4.2\% relaxation, \(n = 8\); fig. 5a). Hyperpolarization and relaxation to caffeine (1 mM: 15.8 \pm 1.4 mV, \(n = 9\) and 70.7 \pm 6.3\%, \(n = 8\), respectively) were attenuated by IbTx (1 mM: 6.0 \pm 2.7 mV, \(n = 4\) and 38.0 \pm 7.5\%, \(n = 4\), respectively; fig. 5a) and by ryanodine (1 mM: 4.4 \pm 1.9 mV and 40.0 \pm 30.9\%, \(n = 6\)).

Application of the NO donor NONOate (3 nM to 1 \textmu M) stimulated concentration-dependent hyperpolarization (log \(EC_{50}\): –7.05 \pm 0.18, \(n = 11–13\); 1 \textmu M: 14.1 \pm 1.1 mV, \(n = 11\)) and relaxation (log \(EC_{50}\): –7.47 \pm 0.05, \(n = 13–14\); 1 \textmu M: 89.0 \pm 1.8\% relaxation, \(n = 13\); fig. 5b). The sGC inhibitor ODQ (1 \textmu M) did not significantly affect hyperpolarization to NONOate (\(n = 6–7\); 1 \textmu M: 12.6 \pm 4.1 mV, \(n = 6\)) but significantly attenuated the relaxation (\(n = 6–7\); 1 \textmu M: 47.8 \pm 13.3\% relaxation, \(n = 7\); fig. 5b). Blockade of BK\textsubscript{Ca} channels with IbTx (100 nM) significantly inhibited...
Fig. 5. Caffeine and NONOate stimulate hyperpolarization and relaxation. Concentration response curves showing hyperpolarization (left panels) and relaxation (right panels) produced by caffeine (a) or the NO donor DEA-NONOate (b) in endothelium-intact (+EC) or endothelium-damaged arteries (–EC; c). Vessels were pre-incubated with L-NAME (100 μM), IbTx (100 nM), ODQ (10 μM) and/or ryanodine (10 μM). Data are expressed as means ± SEM (n = 4–9). *p < 0.05, significant difference from L-NAME (+EC) or control (–EC); †p < 0.05, significant difference from baseline.
both NONOate-induced hyperpolarization and relaxation (n = 3–4; fig. 5b).

**Effect of Removing the Endothelium on Myogenic Tone and the Response to Application of Exogenous NO**

Following removal of the endothelium, cerebral artery smooth muscle cells were depolarized (E$_m$ = $-45.9\pm2.2$ mV, n = 12) and spontaneously developed tension (1.5 ± 0.2 mN, n = 12) sometimes (9 of 12 records) associated with oscillations in both E$_m$ (amplitude: 4.5 ± 1.2 mV; frequency: 0.84 ± 0.20 Hz, n = 12) and tension. In these denuded cerebral arteries, L-NAME did not further increase tension (data not shown).

The NO donor, NONOate (3 nM to 1 μM) evoked concentration-dependent hyperpolarization and relaxation in denuded arteries (logEC$_{50}$: −7.50 ± 0.06; 1 μM: 9.2 ± 2.2 mV and 78.0 ± 7.9% relaxation, n = 6; fig. 5c). Ryanodine (10 μM) caused a small increase in tone, which was associated with slight depolarization (E$_m$ = $-41.7\pm1.0$ mV, n = 12) and a significant increase in the amplitude of oscillations in E$_m$ (23.3 ± 2.7 mV; frequency: 1.24 ± 0.09 Hz, n = 12; fig. 5c). These oscillations were not coupled to a detectable tension change. Ryanodine markedly reduced the hyperpolarization produced by NONOate, but did not significantly affect the relaxation. Interestingly, NONOate reduced the amplitude and frequency of ryanodine-mediated oscillations in E$_m$ (1 μM; fig. 5c). The addition of IbTx did not modify the effects of ryanodine, apart from further increasing the amplitude of oscillations by around 10 mV (amplitude significantly increased to 34.9 ± 3.4 mV, frequency 1.29 ± 0.09 Hz, n = 8; fig. 5c).

To further characterize the action of NO, experiments were performed to assess an action at VGCC. In endothelium-denuded arteries, IbTx had no significant effect on hyperpolarization and relaxation responses to NONOate (1 μM; 7.4 ± 3.1 mV and 99.6 ± 3.4%, n = 6; compare fig. 5c to fig. 6b). However, in the additional presence of ODQ, the hyperpolarization and relaxation to NONOate were reduced (fig. 6a, b). Subsequent addition of the L-type VGCC opener BayK 8644 did not significantly alter membrane potential (hyperpolarization of 3.7 ± 3.8 mV) but contracted arteries (1.2 ± 0.2 mN, n = 5), and significantly increased both the frequency and amplitude of oscillations in E$_m$ (fig. 6c). In the presence of this combination of inhibitors, the hyperpolarization to NONOate was effectively abolished, and the relaxation to NONOate markedly reduced.

**Direct Action of NO on VGCC**

The average resting E$_m$ of isolated smooth muscle cells was $-51.1\pm2.0$ mV (n = 12). In these unstretched and unstimulated cells, E$_m$ tended to oscillate (amplitude of 15.4 ± 2.8 mV, n = 12), but a clear pattern was not observed (fig. 7a). In contrast, under similar conditions at 37°C, the resting E$_m$ of smooth muscle cells isolated from mesenteric arteries tended to remain stable at $-54.5\pm0.6$ mV (with less frequent and lower amplitude oscillations of 5.2 ± 0.5 mV, n = 11). Addition of 1 μM NONOate to the superfusion solution stimulated hyperpolarization and abolished the oscillations in E$_m$ (fig. 7a). In whole cell mode, steady-state I$_{CaL}$ was recorded for 1 min using the ramp protocol. Application of NONOate (1 μM) to the bath induced a significant reduction in I$_{CaL}$, which was not inhibited by ODQ (fig. 7c, d; n = 6–7). The effect of NONOate on I$_{CaL}$ was time dependent (fig. 7d), so values were taken at 10 min following application of NONOate.

**Discussion**

These data from the rat middle cerebral artery indicate that myogenic tone and vasomotion are normally suppressed by basal release of endothelium-derived NO that inhibits VGCC largely via sGC-independent pathways. This can occur either through an effect at RYR and activation of smooth muscle cell BKCa channels, or a direct action independent of voltage. The activation of BKCa channels appears to involve in part an indirect action of NO due to stimulation of Ca$^{2+}$ release from ryanodine-sensitive Ca$^{2+}$ stores, but also in part a direct action of NO on the K$_{Ca}$ channel. Therefore, upon inhibition of NO, smooth muscle cell depolarization due to closure of BKCa channels and the removal of an inhibitory influence, both lead to opening of VGCCs which is followed by a rise in [Ca$^{2+}$]$_{SMC}$ and tension leading to arterial vasomotion.

The finding that myogenic tone is normally suppressed by basal release of NO in rat middle cerebral arteries is consistent with previous studies using cerebral arteries [14–19] and a variety of other vessels that exhibit myogenic tone including small coronary arteries [11, 12]. By suppressing myogenic tone, NO also suppresses vasomotion in the middle cerebral artery. Nifedipine fully reversed the effects of L-NAME, reversing tension and abolishing synchronized oscillations in both E$_m$ and [Ca$^{2+}$]$_{SMC}$. Therefore, it is apparent that opening VGCCs is essential for vasomotion to develop, consistent with many other vessels [1, 36]. Despite this, we cannot rule

sGC-Independent Effects of NO on Cerebral Vasomotion

J Vasc Res 2010;47:93–107
out the involvement of other ion channels. Once the intracellular Ca^{2+} levels rise and the membrane depolarizes, other channels would be stimulated to open, including voltage-gated Na^{+} channels, Ca^{2+}-activated Cl^{-} channels and K_{Ca} channels. Furthermore, as both the endothelial and smooth muscle cells are coupled by homocellular and heterocellular gap junctions in this artery [37], it remains possible that the endothelium influences membrane potential through NO or other mediators. For example, changes in endothelial cell Ca^{2+} are responsible for the release of NO, so endothelial cell K_{Ca} channels may also play a role in the observed changes in membrane potential.

While basal release of NO is known to suppress myogenic tone (and vasomotion), the precise mechanisms are unclear. However, it is likely that NO acts via multiple mechanisms, a few of which are shown in figure 8. NO can suppress the contractile apparatus of the smooth muscle cells via the cGMP pathway. Indeed, ODQ produced increases in tension and depolarization (similar to L-NAME, albeit with a lower frequency of vasomotion), suggesting that sGC somehow stimulates hyperpolarization, perhaps via an action at BK_{Ca} channels through PKG-dependent mechanisms [24, 25] or by an action on RYRs [27, 28]. In addition, our data are consistent with a cGMP-independent action of NO at BK_{Ca} channels, because in the presence of ODQ the BK_{Ca} channel-mediated hyperpolarization induced by the NO donor was reduced, but not significantly, leaving an ODQ-insensitive hyperpolarization. This suggests that endogenous NO activates BK_{Ca} channels either directly [21, 22] or via stimulation of Ca^{2+} release (for example sparks) from ryanodine-sensitive stores (by opening RYRs). Evidence for the latter comes from the ability of ryanodine to block NONOate-induced hyperpolarization in endothelium-damaged vessels. Despite this block, NONOate was still able to reduce the frequency and amplitude of the depolarizing spikes (oscillations in E_{m}) linked with the vasomotion generated by ryanodine. This suggests that NO acts to prevent the opening of the ion channel responsible for the depolarization. Further evidence consistent with a cGMP-independent action of NO on RYRs was the ability of ryanodine to (1) stimulate vasomotion, mimicking the effect of NOS inhibition, and (2) inhibit the IbTx-sensitive hyperpolarization to caffeine.

Although it is likely that a major component of NO-induced suppression of myogenic tone involves a stimulation of Ca^{2+} release events, our data argue against an essential role for NO in the activation of RYRs. In the presence of nifedipine, L-NAME did not markedly prevent the basa asynchronous propagating Ca^{2+} waves, whereas ryanodine did. This is in contrast to previous observations in cerebral arteries by Mandala et al. [26], who suggested that NO was absolutely essential for RYR activation (and thus for activation of BK_{Ca} channels) because spontaneous Ca^{2+} sparks were reduced by around 50% with NOS inhibitors or endothelium removal. However, following on from our observations, it is likely that asynchronous propagating Ca^{2+} waves were masked by the Ca^{2+} influx through the L-type VGCCs and development of synchronous Ca^{2+} oscillations, as observed in the present study. Therefore, while the activation of BK_{Ca} channels by NO likely involves direct stimulation of RYR-controlled Ca^{2+} stores, this action of NO is not an essential step in the activation of RYR. It follows that as RYR stimulation is not necessarily associated with NO, an as yet unidentified process may also modulate vasomotion. In support of this conclusion, inhibition of RYR in the absence of a functional endothelium (and therefore NO synthesis) resulted in a small increase in tension as well as development of large, regular depolarizing oscillations in E_{m}.

Further experiments in the absence of functional endothelium showed that NONOate appears to directly inhibit VGCCs. In the presence of both IbTx and ODQ, NONOate responses mimicked those of nifedipine under control conditions and in the presence of L-NAME, that is, complete block of the oscillations in E_{m} associated with a small hyperpolarization, and relaxation. This di-

**Fig. 6.** Application of exogenous NO (NONOate 3 nM to 3 μM) appears to directly inactivate VGCCs in endothelium-denuded middle cerebral arteries. a Original trace showing that in the combined inhibition of BK_{Ca} channels (IbTx, 100 nM) and sGC (ODQ, 10 μM), NONOate induces a reduction in membrane potential oscillation frequency and amplitude (upper trace) that is associated with relaxation (lower trace). The effects of NONOate were fully reversed by an opener of L-type VGCCs (BayK 8644, 1 μM). Highlighted regions (gray lines) are reproduced in an extended time base to demonstrate that BayK 8644 fully reverses the effects of NONOate. Also shown are concentration response curves (b) showing the effect of NONOate on membrane potential and tension as well as histograms (c) showing the effect of NONOate on oscillation frequency and amplitude in the presence of IbTx, the combined presence of IbTx and ODQ and in the additional presence of BayK 8644. Note that following inhibition of BK_{Ca} and sGC, NONOate-mediated relaxation does not seem to involve a true hyperpolarization but results from a reduction in both frequency and amplitude of the oscillations in membrane potential. Data are expressed as means ± SEM. * p < 0.05, significant difference from control; * p < 0.05, significant difference from baseline.
rect effect of NONOate on VGCC was confirmed in isolated smooth muscle cells, where $I_{CaL}$ was markedly reduced. The effect of NONOate on $I_{CaL}$ in the isolated cells appears to be, at least in part, via a direct action on the channel protein or associated proteins, rather than via a cGMP-dependent mechanism. This is consistent with previous findings in the carotid body, where Summers et al. [33] showed that NO-mediated inhibition of $I_{CaL}$ occurs via S-nitrosylation of the channel protein, and that S-alkylation of the free cysteine residues by NEM prevented the modulation by the NO donor sodium nitroprusside, rather than via the activation of sGC.

Further evidence for the action of NO on $I_{CaL}$ in our studies to be induced by nitrosylation rather than via the cGMP/PKG pathway may come from the time course of NONOate-induced inhibition, which took minutes to tens of minutes to occur. Previous studies of neuronal BK Ca channels suggest that not only does nitrosylation require a higher concentration of NO than the PKG pathway, but it develops with a much slower time course [38, 39].

The action of NO at VGCC was fully reversed by adding the direct opener of L-type VGCC, suggesting that the sites of action are independent. Although there is evidence that both NO and BayK 8644 each evoke their effects on the L-type VGCC via the pore-forming $\alpha_{1c}$-subunit, BayK 8644, which competitively competes with nifedipine, binds from the extracellular surface to access the dihydropyridine receptor site within the channel [40, 41]. The site of NO-induced VGCC modulation by nitrosylation still remains to be elucidated, although there is evidence that VGCC function can be impaired by nitrosylation of an intracellular tyrosine residue (Y2134) situated in the src kinase protein-binding domain of the carboxy terminal of the $\alpha_{1c}$-subunit [42].

In summary, in rat middle cerebral arteries a basal release of NO from the endothelium suppresses myogenic

![Fig. 8. Schematic depicting actions of NO in cerebral artery smooth muscle cells. Release of NO from endothelial cells can suppress vasomotion via multiple mechanisms. (i) Stimulation of sGC can relax smooth muscle cells via voltage-independent pathways. (ii) NO can directly activate BK$_{Ca}$ channels, leading to hyperpolarization, closure of VGCC and relaxation. (iii) The action of NO on BK$_{Ca}$ channel activity can be indirect, via a direct action of NO at RYRs, or (iv) via an intermediate (such as sGC/PKG). RYRs are also activated by NO-independent mechanisms (v) including those related to store filling via the Ca$^{2+}$ ATPase (SERCA). This depiction is based on the close association of RYRs to BK$_{Ca}$-channels, which are spatially separated from the Ca$^{2+}$ release and influx mechanisms associated with contraction [43, 44].

![Fig. 7. NONOate inhibits VGCC via a sGC-independent mechanism. a In isolated smooth muscle cells at 37°C under current-clamp conditions the resting $E_m$ oscillated. Addition of 1 μM NONOate (indicated by arrow) hyperpolarized the cell and abolished the oscillations in $E_m$. b The voltage protocol for detecting $I_{CaL}$ (top) resulted in inward current that was reduced by 1 μM NONOate (bottom). c Mean current voltage relationships under both control conditions (n = 6, left) and after pretreatment with ODQ (n = 7, right) show that the inhibition of $I_{CaL}$ by 1 μM NONOate was not sensitive to ODQ. d The peak current was reduced by approximately 50% under both conditions. Data are expressed as means ± SEM. * p < 0.05, significant difference from control. e Effect of 1 μM NONOate (added at arrow) on peak $I_{CaL}$ amplitude over time, for data shown in c and d. NONOate-induced $I_{CaL}$ inhibition took minutes to occur, and was not due to current rundown (time control).](http://example.com/fig7.jpg)

sGC-Independent Effects of NO on Cerebral Vasomotion
trolling mechanism on myogenic tone in cerebral arteries. The development of vasomotion. Therefore, our data indicate that basal NO release represents an important controlling mechanism on myogenic tone in cerebral arteries. In disease states where NO synthesis is compromised, disruption of this constitutive suppression of myogenic tone would be predicted to increase significantly the risk of brain ischaemia.
