Key Words

Primary renal lymphoma · Chemotherapy · Renal mass · Non-Hodgkin's lymphoma · Radical nephrectomy

Abstract

We report a case of primary renal lymphoma in a 48-year-old man. He was admitted with a large homogenous right renal mass that was revealed by computed tomography scan of the abdomen and pelvis. The patient underwent transperitoneal right radical nephrectomy. Pathologic diagnosis was in favor of primary renal lymphoma.

Introduction

Renal involvement is common in patients with systemic Non-Hodgkin's lymphoma. Primary renal lymphoma (PRL) is a controversial and rare disease. There is no agreement whether or not it is an initial manifestation or a rapidly systemic disease. The term PRL is applied when the disease is localized to the kidney without any sign of other organ involvement or when renal involvement is the presenting manifestation [1]. Flank pain is the most common presenting symptom, and different histologies have been reported.

Case Presentation

The patient was a 48-year-old Iranian male who was admitted due to dull abdominal pain, anorexia and fatigue. The pain began 2 months previously. In the past medical history only controlled hypertension was detected. No history of any surgery was present. BMI was 28. Physical examination showed a palpable mass in the right flank area. Hematological examination results and biochemistry lab data (renal function tests, liver function tests, and other routine lab tests) were within the normal limits, whereas urine analysis showed only microscopic hematuria (10–12 RBCs). An ultrasonographic examination of the abdomen and pelvis showed a large retroperitoneal mass of the right kidney (fig. 2). The contralateral kidney was normal. On the abdominal computed tomography (CT) scan a large

homogenous right renal mass (with 17.5×13 cm size) was detected. Chest X-ray was within normal limits. Due to suspicion of renal cell carcinoma, transperitoneal right radical nephrectomy with lymphadenectomy was performed (fig. 3). The weight of the mass was 3,200 g. Pathologic diagnosis was in favor of Non-Hodgkin's PRL (fig. 2). Bone marrow aspiration was done postoperatively, which was normal. Systemic chemotherapy with 8 courses of CHOPP regimen (cyclophosphamide, adriamycin, vincristine, and prednisone) was initiated without complications. The patient tolerated chemotherapy well and is in good physical condition now, one year after surgery.

Discussion

Although secondary renal involvement from systemic lymphoma is very frequent, PRL is a rare entity, accounting for only 0.7% of all extranodal lymphomas [2], and as a clinical entity it is not undisputed because the kidney does not contain lymphatic tissue and the mechanism of development of PRL is unclear [3]. It is characterized by aggressive histopathology, very early extrarenal infiltration and poor prognosis [4]. PRL is defined as a lymphoma that involves only the kidney at presentation and manifests with renal involvement [3]. Diagnosis is established by renal biopsy, although it often presents as a mass simulating renal cell cancer, and diagnosis is obtained after radical nephrectomy [5]. Most PRLs that have been reported were classified as diffuse, large B cell lymphoma, and almost all PRLs were of B cell lineage [6]. PRL is a distinct pathological and clinical entity which is extremely rare and highly aggressive since disseminating rapidly from its origin. Although there are no clearly defined diagnostic criteria for renal lymphomas, abdominal and thoracic CT as well as renal and bone marrow biopsy are recommended. The disease usually affects adults with an average age of 60 years, and there is a slight male preponderance. Several histogenetic theories of the disease have been postulated since the kidney does not normally contain lymphoid tissue. The neoplastic lymphoid cells may express both B and T immunoblastic phenotypes; primary renal Hodgkin's lymphoma has also been reported. The disease may present with progressive renal failure of either oliguric or non-oliguric type. Imaging studies in diagnosing and staging PRL include ultrasound examination and CT scanning. Whole body bone scan and bone marrow biopsy will complete clinical staging of disease. Renal biopsy is important in assessing the diagnosis of PRL. Multidrug chemotherapy is mandatory for high-grade lymphoma and when the disease is diagnosed preoperatively. Survival is extremely poor since 75% of patients die less than 1 year after operation. Prognosis may be improved by early detection of disease and by performing systemic chemotherapy [7]. One of the differential diagnoses of PRL is mucosa-associated lymphoid tissue (MALT) lymphoma, which is more rare than PRL. MALT lymphoma represents a low-grade B cell marginal zone, the lymphoma arising in extranodal tissue in which lymphoid tissues are usually absent, and it is usually acquired in response to chronic inflammation or in association with an autoimmune disorder. The biological behavior of the disease generally differs from the nodal low-grade B cell lymphoma [8] and responds well to local therapy. In a study by Schniederjan and Osunkoya [9] on the 40 cases of lymphoid neoplasms of the genitourinary tract, the most common site of involvement was the kidney. B cell Non-Hodgkin's lymphomas predominated, with diffuse large B cell lymphoma being the most common subtype in the entire group. Among renal, bladder, and ureter lymphomas, a male predominance was noted (1.6:1).

Several imaging options exist for evaluation of renal involvement including ultrasonography, intravenous pyelography, CT scan, and magnetic resonance imaging (MRI). Ultrasonography shows renal lymphoma as a hypoechoic mass, a finding that reflects homogeneity. CT scan is the imaging modality of choice for evaluation of the kidneys in patients with suspected renal masses including renal lymphoma [6]. The CT

patterns in renal lymphoma include: multiple renal masses (with up to 60% of the cases), renal invasion from contiguous retroperitoneal disease (seen in 25–30% of cases), solitary masses (6% of cases), or diffuse renal infiltration (almost always bilateral and seen in approximately 2% of patients) [10]. Solid renal masses including renal cell carcinoma and metastases are the most common entities that mimic renal lymphoma at CT [11]. Metastases from primary tumors such as breast cancer, lung cancer, or synchronous renal cell carcinoma often present as bilateral masses that are indistinguishable from multifocal lymphoma, so in such cases, accurate history taking is essential [12]. An infiltrative growth pattern may be seen with tumors such as transitional cell carcinoma or with inflammatory processes such as xanthogranulomatous pyelonephritis.

Conclusion

PRL represents a rare entity which must nevertheless be considered in cases of unusual renal masses or otherwise unexplained renal symptoms. Based on our knowledge, this is the first case report of PRL from Iran. Standard management of a renal mass is nephrectomy. PRL is a rare exception in which renal biopsy is needed for diagnosis. Chemotherapy is its first-line therapy and consists of a CHOP regimen associated with rituximab. We believe that both the delayed diagnosis and the histological aggressive behavior of the disease are responsible for the poor prognosis of PRL and that if diagnosed early, cure is possible.

Fig. 1. Histologic HE staining of the nephrectomy specimen revealing B cell lymphoma.

Fig. 2. Abdominal CT scan revealing a near homogenous mass of the right kidney.

Fig. 3. Abdominal CT scan, two weeks after operation and before systemic chemotherapy, revealing no residual tumor or para-aortic lymph nodes.
