Abstract

A critical amount of energy reserve is necessary for puberty initiation, for normal sexual maturation and maintenance of cyclicity and fertility in females of most species. Therefore, the existence of circulating metabolic cues which directly modulate the hypothalamus-pituitary-gonad axis is predictable. The adipocyte-derived hormone leptin is one of these cues having been studied extensively in the context of regulating the reproductive physiology. Humans and mice lacking leptin (*ob/ob*) or leptin receptor (*LepR*, *db/db*) are infertile. Leptin administration to leptin-deficient subjects and *ob/ob* mice induces puberty and restores fertility. *LepR* is expressed in brain, pituitary gland and gonads, but studies using genetically engineered mouse models determined that the brain plays a major role. Recently, it has been made clear that leptin acts indirectly on gonadotropin-releasing hormone (GnRH)-secreting cells via actions on interneurons. However, the exact site(s) of leptin action has been difficult to determine. In this review, we discuss the recent advances in the field focused on the identification of potential site(s) or specific neuronal populations involved in leptin's effects in the neuroendocrine reproductive axis.

Introduction

A critical amount of energy reserve is necessary for puberty initiation, for normal sexual maturation and maintenance of cyclicity and fertility in females of most species [1, 2]. Ovulation is usually suppressed when a mammal is in negative energy balance, whether that state is caused by inadequate food intake, excessive locomotor activity or increased thermoregulatory costs. If excessive leanness occurs in young women, puberty is often delayed [3]. Puberty is a complex process which involves changes in maturation of reproductive organs, physical manifestations of steroids hormones and establishment of the reproductive capacity [4]. The onset of puberty is marked by an increase in gonadotropin-releasing hormone (GnRH) secretion in a defined temporal manner. When puberty develops normally, sexual maturity is achieved and the secretion of gonadotropins becomes pulsatile, consisting of variable but well defined secretory pulses across the estrous (menstrual) cycle. This pulsatile release of GnRH is obligatory to sustain normal gonadotropin synthesis and secretion, cyclicity and ovulation. Food restriction, excessive exercise and other energetic challenges suppress GnRH pulsatility, and thereby disrupt cyclicity and fertility, and may delay the onset of puberty [3, 5, 6]. Therefore, the existence of a number of metabolic cues which impinge on GnRH neurons is predictable. The adipocyte-derived hormone leptin is one of these cues having been studied extensively in the context of regulating the reproductive axis.

Leptin Action on Reproduction

Mice lacking leptin (*ob/ob*) or leptin receptor (LepR, *db/db*) develop hyperphagic obesity, diabetes and a variety of neuroendocrine dysfunctions [7, 8]. These mice exhibit low gonadotropin levels, incomplete development of reproductive organs and do not reach sexual maturation. Leptin treatment to *ob/ob* mice, but not weight loss alone, induces puberty, maturation of the gonads, gonadotropin secretion and restores fertility [9, 10]. Humans with mutations in leptin or LepR genes recapitulate most of the leptin-deficient reproductive phenotype observed in mouse models [11]. In leptin-deficient subjects, leptin treatment induced an increase in the levels of gonadotropins and estradiol, as well as enlargement of the gonads and normal pubertal development [11]. Leptin levels fall on starvation, a response that drives many of the neuroendocrine changes observed in this condition, including those related to the reproductive neuroendocrine axis [12]. Thus, during states of negative energy balance, as in fasting, animals from many species exhibit decreased luteinizing hormone (LH) levels. Leptin administration blunts the fasting-induced suppression of LH secretion and restores fertility [12–14]. In women with hypothalamic amenorrhea resulting from conditions of negative energy balance, leptin treatment increased pulse frequency and mean levels of LH, ovarian volume, the number of dominant follicles and estradiol levels [15]. Therefore, also in humans sufficient levels of leptin are required for normal reproductive function.

An important aspect to be mentioned is that the infertility phenotype observed in animal models of leptin deficiency seems to be highly dependent on their genetic background. For example, obese *ob/ob* mice crossed onto a BALB/cJ strain exhibited improvement of fertility [16]. This phenomenon appears to be sexually dimorphic, as *ob/ob* males on F2 generation are partially fertile, but females only show improvement of fertility following backcrossing of the *ob* C57BL/6J mutation for 10 generations into the BALB/cJ genetic background. Moreover, a series of studies performed in seasonal breeders have challenged the concept of leptin action in the reproductive physiology (reviewed in Schneider [17]). In female hamsters, fasting-induced decrease in leptin levels is not always followed by reproductive impairment. In addition, leptin treatment prevents fasting-induced anestrus in female hamster only when oxidable fuels (e.g. fatty acid or glucose) are available. In food restricted re-fed hamster and sheep, plasma leptin does not increase before the restoration of LH pulses and fertility [17, 18]. These findings

suggest the existence of species differences likely due to exposure to specific evolutionary constraints and development of distinct reproductive strategies. But it also remains unclear whether in these conditions leptin signaling, LepR expression, leptin's transport through the blood brain barrier or the levels of unbound circulating leptin are unchanged.

The LepR is expressed in many different organs and tissues, including every node of the hypothalamus-pituitary-gonad axis [8, 19]. Thus, the ability of leptin to regulate reproduction might be attained by direct actions in several cell types. Nevertheless, using genetic strategies, studies showed that selective re-expression of LepR only in the brain of mice otherwise *null* for LepR restores fertility in both males and females [20]. These studies established that the brain plays a major role.

The direct action of leptin in GnRH neurons seemed reasonable, as in vitro studies reported the expression of LepR in immortalized GnRH (GT1) cells [21]. However, these findings have not been reproduced in vivo (fig. 1) and, therefore, leptin direct action in GnRH neurons remained controversial. More recently, with the availability of genetic mouse models which allow selective deletion of LepR from defined neuronal populations, this controversy appears to have come to an end. Mice with selective deletion of LepR from GnRH neurons exhibited normal puberty initiation, sexual maturity, fertility and normal litter sizes [22]. This study determined that if LepR is expressed in GnRH neurons – in low or technically undetectable levels – it is not required for leptin action in puberty initiation and in the coordinated control of the reproductive function. Hence, the identification of leptin-responsive cells afferent to GnRH neurons has been of great interest to the field.

The signaling (long) form of the LepR (LepRb) is expressed in several brainstem sites and in many hypothalamic nuclei such as the arcuate, the ventromedial, the dorsomedial and the ventral premammillary [23, 24]. In the following sections, we will discuss the recent advances in defining the leptin-responsive neural pathways involved in reproductive control.

Brainstem

In the brainstem, LepRs and leptin-induced phosphorylation of signal transducer and activator of transcription 3 (pSTAT3) are found in several nuclei, including the dorsal raphe, the lateral parabrachial, the Edinger-Westphal and the nucleus of the solitary tract (NTS) [24–26]. Of

those, special attention has been given to the NTS (fig. 2a). Neurons in the NTS receive sensory inputs conveyed by the vagus nerve and signals from circulating factors conveyed through the area postrema. The area postrema is a closely associated circumventricular organ – positioned outside the blood brain barrier – located in the dorsal border of the medial NTS. Several lines of evidence have indicated that sensory vagal inputs and circulating metabolic cues (e.g. glucose) may reach the reproductive control sites of the central nervous system via the NTS. For example, during fasting, disruption of visceral sensory signals achieved by bilateral vagotomy restored the decreased LH levels characteristic of this condition [27]. Site-specific deprivation of glucose availability in the caudal brainstem decreased LH secretion, suggesting that the area postrema may act as a glucosensor in the modulation of gonadotropins [28]. However, viral delivery of LepR into the NTS of LepR-deficient Koletsky rats did not restore their reproductive function [29]. In addition, selective deletion of LepR only from forebrain nuclei, maintaining intact the expression of LepR in the brainstem,

recapitulated the reproductive deficit of leptin-signaling deficiency [22]. These findings suggest that although the caudal brainstem may carry signals from visceral inputs and glucose availability to the reproductive system, it does not relay leptin's effects in reproductive control.

Paraventricular Nucleus of the Hypothalamus

Food deprivation is a recognized condition of nutritional stress characterized by low leptin levels, decreased LH secretion and high corticotrophin-releasing hormone (CRH) levels. Interestingly, pharmacological blockade of CRH during fasting normalized LH levels [30]. Moreover, prevention of the decrease in leptin levels induced by fasting blunts the activation of the hypothalamus-pituitary-adrenal (HPA) axis and prevents the suppression of the reproductive axis [12]. Together, these findings suggested that CRH neurons might mediate leptin's effect to increase LH secretion in states of negative energy balance. It is well defined that the CRH neurons involved in the

Fig. 2. Distribution of neurons expressing LepR in the NTS and PVH. regulation of the HPA axis are located in the paraventricular nucleus of the hypothalamus (PVH). But the expression of LepR in the PVH is very low (fig. 2b) and the colocalization of LepR in CRH neurons of the PVH is still debatable. This anatomical piece of data indicates that leptin's effect on CRH secretion is achieved via indirect pathways, which are still unrevealed.

Arcuate Nucleus

In the arcuate nucleus (Arc), LepRs are colocalized with proopiomelanocortin (POMC), neuropeptide Y/agouti-related protein (NPY/AgRP) and *Kiss1* neurons [31–33]. It has been determined that POMC and NPY/AgRP neurons mediate most of leptin's effects in food intake, body weight and glucose homeostasis. These neuronal groups have also been investigated as likely players linking metabolism and reproduction.

The role of POMC neurons in the control of GnRH secretion and the melanocortin action mediating leptin's effect on reproduction have been subjects of intense debate with inconclusive results. For example, administration of α -melanocyte-stimulating hormone (α -MSH, one of POMC products) in rats may stimulate or inhibit LH secretion depending on their physiological condition [34]. The lethal yellow (Ay) mice, which display constitutive and ubiquitous expression of the agouti protein – a competitive antagonist of melanocortin receptors, exhibit obesity and abnormal estrous cycles [35]. In normally fed or leptin-treated fasted rats, melanocortin antagonists decreased the steroid-induced LH surge [36]. However, melanocortin 4 receptor (MC4R) knockout mice have no evidence of infertility [37] and pharmacological blockade of MC4Rs does not prevent the ability of leptin to positively regulate the reproductive axis of *ob/ob* mice [38]. Moreover, mice with selective deletion of LepR from POMC neurons, from AgRP neurons, or from both POMC and AgRP neurons are fertile and produce normal litter sizes [39, 40]. Recently, we described that deletion of both LepR and insulin receptor from POMC cells causes insulin resistance, hyperandrogenism and ovarian abnormalities with late onset of subfertility [41]. Thus, it is not yet clear whether the reproductive deficits observed in some models of melanocortin signaling deficiency are caused by disruption of a direct neuronal regulation of GnRH secretion or are secondary to their impaired metabolic function.

A role for the NPY system in reproduction has also been proposed. Central administration of NPY stimulates feeding and inhibits the reproductive axis [42]. However, the actions of NPY on GnRH secretion remain somewhat controversial. Studies in different species have suggested the existence of a complex dual action of NPY – one inhibitory and one stimulatory – through which endogenous NPY may regulate the hypothalamus-pituitary-gonad axis. These opposing effects depend on several variables, such as the steroid hormone milieu, the stages of development and changes in the

expression of sex steroids receptors [6, 43]. Likewise, the involvement of NPY neurons in leptin action on reproductive control is unclear. Deletion of NPY gene expression in mice also lacking leptin (*ob/ob* mice) improves fertility, but NPY *null* mice display normal reproductive function [44]. Moreover, as mentioned, deletion of LepR from AgRP/NPY neurons causes no fertility deficits [40]. Although very compelling, the experiments using genetically modified mouse models must be interpreted with caution as developmental compensatory mechanisms may have mask some of the relevant effects of POMC or NPY neurons on leptin's effect on reproductive control.

In the Arc, a subset of LepR neurons expresses *Kiss1* [33]. The role of kisspeptins (the products of *Kiss1* gene) and their receptor (*Kiss1r*, identified as GPR54) in the reproductive physiology is well established. Hypothalamic levels of *Kiss1* and *Kiss1r* mRNA increase during pubertal development and administration of kisspeptin induces vaginal opening (in juvenile rodents), increases LH secretion and induces ovulation [45, 46]. *Kiss1* or *Kiss1r* loss-of-function mutations cause hypogonadotropic hypogonadism in humans and mice [47–49]. Studies have also indicated that kisspeptin neurons are likely targets of metabolic cues as food restriction decreased *Kiss1* mRNA expression in total hypothalamus or in *Kiss1* neurons from the anteroventral periventricular nucleus (AVPV) [50, 51]. As mentioned, food restriction usually produces a condition of low leptin levels; therefore, changes in *Kiss1* mRNA expression may be consequent to changes in circulating levels of leptin. In support to this view, leptin-deficient *ob/ob* male mice exhibited decreased expression of *Kiss1* in the Arc, which is partially restored by leptin treatment [33]. But, intriguingly, total hypothalamic expression of *Kiss1* (which includes the preoptic area and the Arc) was not changed in *ob/ob* mice compared either to wild types or to leptin-treated *ob/ob* mice, except when matched with food-restricted untreated *ob/ob* mice [52]. This finding indicates that leptin may not be the major metabolic factor regulating *Kiss1* expression in conditions of negative energy balance. Another study reported that diabetic streptozotocin-injected male rats displayed decreased levels of hypothalamic *Kiss1* mRNA and low circulating levels of leptin, insulin, LH and androgens [53]. Intracerebroventricular administration of leptin, but not insulin, normalized the hypothalamic *Kiss1* gene expression, and the circulating levels of LH and androgens. However, it is not clear whether leptin's effect to normalize *Kiss1* gene expression is achieved by a direct action

Fig. 3. Comparative distribution of estrogen receptor- α immunoreactivity (ER α -ir) and leptin-responsive neurons in the VMH. **a** Bright-field photomicrograph showing the distribution of ER α -ir in the VMH. Observe that neurons expressing ER α -ir are enriched in the ventrolateral subdivision of the VMH (VMHvl). **b** Bright-field photomicrograph showing the distribution of leptin-responsive neurons in the VMH. Leptin-responsive neurons were visualized by leptin-induced phosphorylation of STAT3 immunoreactivity (pSTAT3-ir). or via activation of an indirect pathway that in turn modulates *Kiss1* system. Previous studies showed that stereotaxic delivery of LepR into the Arc of LepR-deficient obese Koletsky rats normalized their estrous cycle [29]. These findings suggest that neurons in the Arc, including those expressing *Kiss1*, play a major role. But the approach used may have generated an artificial response, as LepR may have been expressed in neurons which are not responsive to leptin under normal circumstances. In a more controlled condition, endogenous re-expression of LepR in the Arc of LepR null mice did not restore the reproductive deficits characteristic of leptin deficiency [54]. But in this experimental design

injections may have not targeted *Kiss1* neurons, and therefore, the role played by *Kiss1* neurons relaying leptin's effect is still unsettled.

Recently, several studies have suggested the existence of a complex interplay among *Kiss1*, POMC and NPY/AgRP neurons in the Arc [55, 56]. Hence, it is been proposed that the coordinated action of this intrinsic circuitry may orchestrate the fine control of GnRH secretion by metabolic cues. Further studies are necessary in order to directly assess the physiological relevance of direct leptin signaling in *Kiss1* neurons and to reveal their role in the intricate circuitry of the Arc neuronal populations.

Table 1. Examples of studies employing genetic or pharmacological manipulations to disclose site-specific or cell-specific effects of leptin

	Reproductive phenotype	Ref.
Global deletion/blockade		
LepR in the brain	infertility, no pubertal development	20
LepR in the forebrain	infertility, no pubertal development	22
Ubiquitous melanocortin antagonism (Ay mouse)	abnormal estrous cyclicity	35
Melanocortin antagonism (pharmacology)	decreased steroid-induced LH surge; normal leptin effect on reproduction (<i>ob/ob</i> mice)	36, 38
MC4R deficiency	no deficits reported	37
NPY knockout	normal fertility	44
NPY knockout in <i>ob/ob</i> mouse	partial improvement of fertility	44
Cell-specific deletion		
LepR from GnRH neurons	normal fertility, normal litter size	22
LepR from POMC neurons	normal fertility, normal litter size	39
LepR from AgRP/NPY neurons	normal fertility	40
LepR from AgRP/NPY and POMC neurons	normal fertility, normal litter size	40
LepR and InsR from POMC neurons	hyperandrogenism, ovarian abnormalities and fertility deficits	41
LepR from SF-1 neurons	normal fertility, normal litter size	61, 62
Site-specific reactivation		
Exogenous LepR in the NTS	no rescue of fertility	29
Exogenous LepR in the Arc	improvement of cyclicity in Koletsy rats	29
Endogenous LepR in the Arc	no rescue of fertility	54

The consequences of the manipulations for the animal reproductive function are summarized in the second column.

Ventromedial Nucleus of the Hypothalamus

The ventromedial nucleus of the hypothalamus (VMH) is a complex structure composed of distinct subdivisions with differential connectivity. The ventrolateral subdivision of the VMH expresses a dense concentration of sex steroids receptors (fig. 3a) and is well described to play a role in the female sexual behavior [57–59]. Neurons in the dorsomedial subdivision of the VMH express the steroidogenic factor-1 (SF-1), LepR and leptin-induced pSTAT3 immunoreactivity (fig. 3b). Deletion of SF-1 selectively from the central nervous system caused disruption of VMH neuronal connectivity and impairment of the female reproductive function [60]. Therefore, the VMH is thought to be a potential leptin target in reproductive control. Using the SF-1 gene promoter to drive Cre expression specifically in VMH neurons, two different groups have demonstrated the physiologic role played by the VMH in leptin's effect on energy homeostasis [61, 62]. However, deletion of LepR selectively from VMH neurons did not produce any reproductive deficits in these mice, indicating that leptin signaling in the VMH is not required for leptin's effect on reproduction.

Ventral Premammillary Nucleus

The ventral premammillary nucleus (PMV) expresses a dense collection of LepR (fig. 4) and leptin-responsive neurons [23, 63, 64]. However, it has remained an unrecognized leptin target and the physiological role played by the PMV in mediating leptin's effects has only recently started to be systematically investigated [64, 65]. The PMV expresses sex steroids receptors [59, 66] and innervates brain sites related to reproductive control, to the vomeronasal system and to the sexually dimorphic circuitry [67, 68]. Using standard tract tracing, we showed that terminals from PMV neurons were in close apposition with GnRH cells in the preoptic area [68]. This preliminary observation was subsequently confirmed by different laboratories using genetically engineered mouse models [64, 69]. Additionally, Leshan et al. [64] demonstrated that, in fact, the innervation of GnRH cells by PMV fibers originates from neurons expressing LepR.

The PMV neurons display Fos immunoreactivity – a maker of neuronal activation – following copulation [70]. But copulation is a complex process making the in-

creased Fos expression difficult to interpret. Subsequent studies showed that the exposure to female odors alone is sufficient to induce Fos in PMV neurons [64, 71–73]. In response to opposite sex odors, male and female from many species exhibit increased circulating levels of gonadotropins [74, 75]. In rats, this effect was suppressed by lesions of the PMV [75, 76]. Together, these findings suggested that the PMV integrates sexually relevant (odor) environmental signals, the reproductive status (sex steroids) and metabolic cues (leptin). We then hypothesized that PMV neurons relay leptin's effect to increase LH secretion during states of negative energy balance.

As a first approach to test our hypothesis, we performed bilateral excitotoxic lesions of the PMV and assessed different parameters of the female reproductive physiology [65]. PMV-lesioned rats displayed a clear disruption of the estrous cycle for 2 to 3 weeks. After this period, their cyclicity was normalized, but lesions of the PMV caused a permanent deficit in the female's neuroendocrine profile. On proestrus, PMV-lesioned rats exhibited reduction of estradiol and LH levels, of GnRH mRNA expression and a blunted activation of GnRH and AVPV neurons. Of note, in PMV-lesioned fasted rats, leptin treatment failed to increase LH levels. Our findings indicate that PMV neurons are required for leptin stimulation of LH secretion in fasted rats. However, it is worth mentioning that the PMV is comprised of a heterogeneous population of neurons, and therefore, the effects produced by the excitotoxic lesions may be the consequence of disruption of pathways not related to leptin's physiology. Thus, a more selective approach in which leptin signaling is either blocked or endogenously re-expressed in PMV neurons is necessary to determine its physiologic relevance for leptin's effect on reproduction.

Conclusion and Future Directions

The coordination of the reproductive control is essential for the species survival. As noted by different authors, the control of the reproductive physiology involves redundant brain pathways and a number of endocrine players. In this review, we discussed the brain sites potentially involved in leptin's physiological effects in the reproductive neuroendocrine axis. The definitive answer has not been offered, but the availability of genetically engineered mouse models and site-specific manipulations of defined genes have brought a considerable advance to the field (table 1). Neuron-specific targeting with the use of transgenic mouse lines and viral vector delivery in defined brain sites will allow the identification of specific neuronal population(s) relaying leptin's effect in reproductive control. Importantly, these approaches must allow the identification of relevant site(s) of leptin effect during development and in adult life. It is also hoped that modern technologies using *in vivo* and *in vitro* approaches to assess site-specific epigenetic changes or alterations in gene expression under metabolic challenges will bring advances to the field. The identification of the related neuronal populations and the molecular basis of leptin's effect on reproductive control is a fundamental step for the understanding of a variety of conditions of impaired fertility derived from metabolic dysfunctions.
