Key Words

Fusiform basilar aneurysm · Ischemic stroke · Subarachnoid hemorrhage

Abstract

We present the case of a patient with acute brain stem ischemic stroke who was found to have a fusiform basilar aneurysm with a thrombus within the dilated vessel. Three days after the ischemic stroke, the patient had a massive subarachnoid hemorrhage and died. This case illustrates the difficulties in the acute management of ischemic events in patients with basilar fusiform aneurysms, because the natural history of this disease encompasses both bleeding and thrombosis.

Introduction

Dolichoectatic and fusiform aneurysms represent a small subset of cerebral aneurysms and are among the most difficult to treat [1]. The pathophysiology of fusiform cerebral aneurysms includes a disrupted internal elastic lamina and muscle layer that might be susceptible to mechanical injury by hemodynamic strain, causing progressive attenuation of the arterial wall [2]. The treatment of fusiform aneurysms of the basilar artery is challenging for several reasons, including the presence of perforating vessels, the proximity to the brain stem and the exiting cranial nerves, and the surgical approaches necessary to access the basilar artery [3–5]. We present the case of a patient with acute brain stem ischemic stroke who had a fusiform basilar artery aneurysm complicated by a

massive subarachnoid hemorrhage. Our objective is to discuss the difficulties in the acute management of this disease, its potential treatments and complications.

Case Report

A 53-year-old man with a previous history of hypertension and obesity was admitted to our emergency department with sudden right hemiplegia, hemianopsia, and dysarthria within 2 h from symptom onset. His National Institutes of Health Stroke Scale (NIHSS) score at admission was 19, and he had no previous history of stroke or transient ischemic attacks. The patient's neurological symptoms progressively improved during the first hour after admission, with only a right facial palsy (NIHSS 2) remaining. A head CT at admission showed a hyperdense basilar artery, and a CT angiography (CTA) confirmed a basilar fusiform aneurysm with a thrombus within the vessel and no signs of acute dissection (fig. 1a–c). A brain MRI showed diffusion restriction within the left mid pons (fig. 1d). He was treated with antiplatelets and transferred to our intensive care unit. Due to his clinical improvement, thrombolysis, endovascular procedures, and anticoagulation were deferred. Three days after admission, the patient suddenly became comatose. A head CT revealed an extensive subarachnoid hemorrhage in the basal cisterns and posterior fossa (Fisher grade 3; fig. 1e, f). The patient died the next day.

Discussion

Basilar artery fusiform aneurysms pose difficulties to treatment because, during the course of the disease, both bleeding and thrombosis can occur. In addition, bleeding may be a complication of a basilar artery fusiform aneurysm in patients initially presenting with brain ischemia, even when anticoagulation and thrombolytic treatments are not used, as happened in our patient [2–5].

Fusiform cerebral aneurysms can be divided into acute dissecting aneurysms, which usually cause subarachnoid hemorrhage or cerebral ischemia, and chronic fusiform or dolichoectatic aneurysms, which slowly enlarge with time and can be asymptomatic or associated with cranial nerve dysfunction, ischemic stroke, subarachnoid hemorrhage, pseudotumor, or hydrocephalus [6]. Although important for the treatment decision-making, the differentiation between a dissecting and a chronic fusiform aneurysm is often difficult, even with advanced neuroimaging techniques [1, 4, 6]. In our patient, regardless of the acute presentation of an ischemic event and posterior bleeding, no signs of dissection were seen on the CTA or the MRI/MRA of the brain.

More than half of large cerebral aneurysms with a diameter of 20 mm or more are known to have thrombi like the one seen in our patient [7]. The mortality rate of patients with fusiform basilar aneurysms is approximately 70% if the basilar artery has become occluded [8, 9]. Conversely, the occurrence of hemorrhagic events is associated with the degree of ectasia of the basilar artery [10]. Anticoagulation therapy at conventional doses seems to increase the risk of intracranial bleeding [11, 12]. The role of antiplatelet agents in promoting hemorrhagic strokes in such patients is less clear [10].

The treatment of such lesions can be a dilemma, as in the case described. In patients with vertebrobasilar dolichoectasia, the risk of brain ischemia is clearly higher than that of intracranial bleeding [13–15]. Considering that the current treatment risks can exceed the natural risk of basilar rupture or occlusion, a better understanding of the pathophysiology is required to help select patients at higher risk of hemorrhagic or ischemic events for invasive treatments [4, 5].
