Abstract

Natural killer (NK) cells are a key component of innate immunity involved not only in the elimination of virus-infected or tumor cells but also in the regulation of the immune response by producing cytokines and chemokines that can activate other cellular components of innate and adaptive immunity. NK cell subsets are differentially affected by aging. Whereas CD56^{bright} cells are decreased in healthy elderly individuals, the CD56^{dim} subset is expanded. The expression of CD57, a marker of highly differentiated NK cells, is increased in the elderly; this supports the notion that a remodeling process of NK cell subsets occurs in aging with a gradual decrease in more immature CD56^{bright} NK cells and an increase in highly differentiated CD56^{dim} CD57+ NK cells. This NK cell redistribution can explain many of the phenotypic and functional changes in NK cells associated with healthy aging such as decreased proliferation and the maintenance of CD16-dependent cytotoxicity.

Introduction

Scientific and clinical advances in the last century have led to a worldwide increase in life expectancy. This, combined with falling birth rates in most countries, has led to a striking increase in both the relative and the absolute numbers of persons over 65 years of age not only in economically developed countries but also in developing countries. This increase in life expectancy has led to a striking increase in the frequency of diseases associated with aging, including infections [1, 2], an increased incidence of cancer [3, 4], and an increase in neurodegenerative and cardiovascular diseases [5, 6]. Many of these diseases are linked to age-associated deterioration of the immune system, a process termed immunosenescence.

Immunosenescence is defined as the state of age-associated dysregulation of the immune function demonstrated in diverse species, including humans, that contributes to morbidity and mortality due to the greater incidence or reactivation of infectious diseases, as well as possibly autoimmune phenomena and cancer [2, 7–9]. The capacity of the immune system to cope with infec-

tious diseases is lower in the elderly than in the young, probably as a consequence of altered immune responses to pathogens [10], indicating that the ability to respond efficiently to pathogens is eroded by immunosenescence.

Although it has been generally accepted that some aspects of innate immunity are well preserved in aging [11], cumulative evidence in the last decade supports the notion that immunosenescence affects not only adaptive immunity but also innate immunity. Thus age-associated alterations of cells of the innate immune system are involved in the increased susceptibility of elderly individuals to infectious diseases. In particular, alterations in the number, phenotype, and functions of natural killer (NK) cells have been shown in the elderly [8, 12].

NK Cell Subsets

NK cells are bone marrow-derived lymphocytes that participate in the early defense against intracellular pathogens and tumor cells. They are cytotoxic non-T lymphocytes that do not rearrange the genes encoding the T cell antigen receptor and characterized by the expression of CD56 and/or CD16 [13]. NK cells are part of innate immunity, acting within hours of infection in contrast to CD8 T cells that require several days to proliferate and differentiate to cytolytic effector T cells. Peripheral blood NK cells represent 10–15% of all lymphocytes. Although NK cells have been considered for many years as being a simple, homogenous, and unspecific population in comparison with T or B cells of adaptive immunity, different subsets have been defined according to the expression of NK markers and their capacity to kill or produce cytokines. Human NK cells are classically divided into 2 functional subsets based on their cell surface density of CD56, i.e. CD56^{bright} immunoregulatory cells and CD56^{dim} cytotoxic cells. Both subsets have been characterized extensively regarding their different functions, phenotype, and tissue localization. The CD56^{bright} NK cell subset has a distinctive role in the innate immune response as the primary source of NK cell-derived immunoregulatory cytokines [14–16] although CD56^{dim} NK cells can produce higher levels of cytokines and chemokines upon target cell recognition compared to CD56^{bright} cells, as emphasized by Fauriat et al. [17]. CD56^{dim} and CD56^{bright} subsets also differ in the expression of chemokine receptors that may contribute to cell trafficking [14, 18, 19]. In addition CD56^{dim} NK cells can be subdivided into functionally heterogeneous subsets ('educated' or

'licensed' vs. 'unlicensed' or 'unlicensed' NK cells), based on the expression of other cell surface receptors, including inhibitory and activating KIR and NKG2A, which can interact with self-HLA class I ligands. Licensing of NK cells by self-MHC class I has been proposed as a mechanism for NK cell tolerance to self. This process results in 2 types of tolerant NK cells: (a) licensed NK cells that are functionally competent and whose effector responses are inhibited by self-MHC class I molecules through the same receptors that conferred licensing, and (b) unlicensed, functionally incompetent NK cells. This process was defined for mouse NK cells and several findings suggest that human NK cells also undergo this licensing process [13, 20–23]. The acquisition of functional competence through 'licensing' by self-MHC molecules implies that effector-target interactions are governed by the integration of inhibitory and activating signals that determines whether the NK cell is finally activated, secretes cytokines, and lyses target cells [24].

In addition to this functional tuning by self-HLA class I ligands during NK cell education, it has been recently suggested that the NK cell number is maintained by a continuous differentiation process associated with the expression of CD57 that ends in NK cells with poor responsiveness to cytokine stimulation but high cytolytic capacity [25, 26]. CD57+ NK cells show increased responsiveness to target cells and decreased responses to cytokines [25]; they are highly mature and display a mature phenotype, a higher cytotoxic capacity, a higher sensitivity to stimulation via CD16, a decreased responsiveness to cytokines, and a decreased capacity to proliferate compared to the CD57- counterparts [26], supporting the notion that a gradual shift in functionality occurs during differentiation from CD56^{bright} via CD56^{dim} CD57- to CD56^{dim} CD57+ NK cells (fig. 1).

This differentiation process is uncoupled from the functional tuning by self-HLA class I ligands during NK cell education, indicating that differentiation and education are parallel but uncoupled processes [25].

Clinical Significance of NK Cells in the Elderly

Several alterations have been described in NK cells with advancing age both in animals and in humans (table 1). The somehow contradictory results are likely due to the different criteria used for the inclusion of study subjects in the diverse studies of elderly humans. While some authors have used the strict SENIEUR criteria [27, 28] of very healthy elderly individuals or healthy cente-

Table 1. Effect of aging on the NK cell compartment

Parameter	Aging
<i>Number</i>	
Number/percentage of NK cells ^a	preserved or increased
CD56 ^{bright} subset	decreased
CD56 ^{dim} subset	preserved or increased
In vivo proliferation and production rates	decreased
<i>Function</i>	
Natural cytotoxicity	decreased or preserved
ADCC	maintained
Proliferation	decreased
Response to cytokines	decreased or preserved
Cytokine and chemokine production	decreased
Intracellular signaling	decreased
<i>Phenotype</i>	
CD57 expression on CD56 ^{dim} cells	increased
CD94/NKG2A expression	decreased
KIR expression	increased
Perforin content	decreased or preserved

^a A decreased frequency is associated with an increased risk of infection, inflammation, or death.

narians, other authors have studied unselected populations of elderly people, analyzing the association of NK cell alterations with diseases or even with the risk of death. The studies using very healthy elderly people and centenarians show that the overall NK cell number tends to increase with age and that NK cytotoxicity is not significantly affected [29–35].

However, studies of unselected elderly populations have shown that the decreased NK cell function in old individuals is associated with an increased incidence of infectious diseases and death due to infection in elderly humans [36, 37], and elderly people (aged >85 years) with low numbers of NK cells have been reported to have an increased mortality risk in the first 2 years of follow-up compared to those with high NK cell numbers [38]. It has also been reported that decreased NK cell activity in the elderly is also associated with an increased frequency of disorders such as atherosclerosis [39] and that a preserved NK function is related to a better health status and a lower incidence of respiratory tract infections in elderly individuals and to a better response to influenza vaccination [40]. Additional evidence supporting the significance of NK cells in healthy aging comes from studies in nonagenarians and centenarians who, in general, have well preserved numbers and func-

Fig. 1. Lineal model of the differentiation of peripheral blood NK cells. CD56^{bright} NK cells are more immature NK cells and the precursors of CD56^{dim} cells. Subsequent differentiation leads to phenotypic and functional changes associated with the acquisition of CD57. Aging is associated with a shift of these subsets with a reduction of CD56^{bright} and expansion of CD56^{dim} CD57+ NK cells.

tions of NK cells [35, 41, 42]; this is also associated with a better ability to maintain an autonomous life style, higher serum vitamin D levels, a well-nourished status, a balanced basal metabolism, and higher concentrations of micronutrients [11, 43, 44]. Together, these results support the fact that preserved NK cytotoxicity can be considered a marker of healthy aging, whereas low NK cytotoxicity is a predictor of increased morbidity and mortality due to infections.

It has also been shown that aging has an impact on NK cell kinetics [45]. These cells are in a state of dynamic homeostasis consistent with a model of postmitotic maturation preceding circulation and with a turnover time in blood of about 2 weeks. NK cells from healthy elderly subjects have proliferation and production rates which are significantly lower than those of NK cells from young healthy individuals [45], indicating that although NK cell numbers are well preserved in healthy aging there is a reduction in total NK cell production rates of 50% and suggesting an increased proportion of long-lived NK cells in the elderly subjects. This may be related to the increased proportion of CD56^{dim} cells, as previously reported in elderly subjects [29]. Furthermore, the increased expression of CD57 observed in NK cells from elderly donors [29, 32] also supports the ac-

cumulation of terminally differentiated NK cells in the elderly subjects. The decreased proliferation and production rates of NK cells in the elderly can be associated with the telomere shortening observed in the elderly. Thus it has been demonstrated that NK lymphocytes show an age-associated loss of telomeres together with an age-associated reduction of telomerase activity that is evident in individuals over 80 years of age, in particular in the oldest individuals and in those with increased NK cell numbers [46, 47].

Effect of Aging on NK Cell Subsets

As discussed above, the NK cell frequency and absolute value tend to increase in healthy aging. However, a redistribution of NK cell subsets is also found in the elderly with a profound decrease of CD56^{bright} NK cells and a concomitant expansion of the CD56^{dim} subset [29, 30, 32], suggesting that the increase in NK cell frequency with age results from expansion of the mature CD56^{dim} subset rather than of the immature CD56^{bright} NK subset. Furthermore, the expression of CD57 is increased on CD56^{dim} NK cells from elderly donors. CD57 (HNK-1 epitope, sialyl-Lewis X) is a sulfated trisaccharide preferentially added to N-glycans of neural cell adhesion molecules, which is expressed on CD56^{dim} NK cells and on CD28[−] CD8⁺ T cells [48, 49]. It has recently been shown that CD57⁺ CD56^{dim} cells represent a highly differentiated subset of NK cells. Thus, a continuous differentiation process of NK cells associated with the expression of CD57 that ends in cells with poor responsiveness to cytokine stimulation and retained cytolytic capacity has been proposed. CD57⁺ NK cells show an increased responsiveness to target cells and decreased responses to cytokines; this supports the notion that a gradual shift in functionality occurs during differentiation from CD56^{bright} via CD57[−] CD56^{dim} to CD57⁺ CD56^{dim} NK cells [25]. Transcriptional, phenotypic, and functional differences between CD57⁺ and CD57[−] NK cells also support the notion that CD57⁺ NK cells are highly mature and might be terminally differentiated, displaying a mature phenotype, a higher cytotoxic capacity, a higher sensitivity to stimulation via CD16, a decreased responsiveness to cytokines, and a decreased capacity to proliferate compared to the CD57[−] counterparts [26]. Thus the decline in CD56^{bright} NK cells and the increase in the CD56^{dim} CD57⁺ subset support the notion that the population of NK cells suffers a process of remodeling with a reduction in the output of more immature CD56^{bright}

cells and an accumulation of highly differentiated CD56^{dim} CD57⁺ NK cells (fig. 1). This possibility can explain many of the phenotypic and functional features of NK cells in the elderly such as the altered expression of some NK receptors, decreased proliferative response to cytokines, or preservation of the CD16-mediated cytotoxic capacity.

This remodeling of NK cell subsets can also contribute to the dysregulation of other cells of the adaptive and innate immune system since CD56^{bright} cells are critical to the cytokine response of these cells; they can play an important role in the activation of dendritic cells (DCs) and interact with monocytes promoting inflammation [14, 19].

Effect of Aging on the Expression and Function of NK Cell Receptors

CD16 is the low-affinity IgG Fc receptor (FcγRIII-A). It is expressed on NK cells and its cross-linking by antibody-coated target cells triggers the so-called antibody-dependent cell cytotoxicity. CD16 associates with immunoreceptor tyrosine-based activation motif (ITAM)-containing chain (CD3ξ or FcεRIγ) complexes. Signaling via CD16 activates the PI-3-kinase pathway and results in the production of cytokines, including IFN-γ, GM-CSF, and several chemokines, and causes degranulation of NK cells [50]. Neither CD16 expression nor CD16 function is affected by aging [11, 32, 39, 51–53], although it is of interest to note that cord blood and infant NK cells display very low CD16-dependent cytotoxicity [32].

Although the overall NK cell cytotoxicity is not significantly affected in very healthy elderly donors, it has been demonstrated that there is a decreased cytotoxicity of K562 target cells per NK cell and that the maintenance of the overall NK cell activity is probably due to the increase in NK cells [32, 44, 53, 54]. The decreased per-cell NK cytotoxicity against the classic target cell line K562 suggests that the expression and/or functionality of other NK-activating receptors are likely to be defective in the elderly.

Little is known about the effects of aging on the expression and function of NK receptors other than CD16, and discrepant results have been reported in this context. While it was reported that the expression of HLA-specific killer immunoglobulin-like receptors (KIR) is not significantly affected in NK cells from elderly compared to young donors [44], another study showed an age-related increase in KIR expression and a reciprocal decrease in

CD94/NKG2A expression [51]. A decreased expression of CD94 and of the coinhibitory receptor KLRG-1 on NK cells from old donors has been shown [55]. KLRG-1 has been postulated to be a marker of senescence in antigen-experienced T cells, although very little is known of its function in NK cells. In a recent study [32], no significant differences in KIR or CD94/NKG2A expression were observed between healthy adults and elderly donors, probably due to the high variability of the results and the broad age ranges considered. In that work [32], a group of cord blood samples was included and, interestingly, it was observed that cord blood NK cells displayed phenotypic features such as the lack of expression of CD57 and LIR-1/ILT-2 or the low expression of KIR and high expression of NKG2A that could be linked to NK cell immaturity. Nevertheless, they express perforin [56] and produce high levels of IFN- γ upon stimulation [32]. NK cells from cord blood have a low cytolytic capacity [32], but their cytolytic activity in infants is comparable to adult NK cytotoxicity [56].

In relation to the effect of aging on the expression of other NK receptors involved in NK cell cytotoxicity, a decreased expression of the activating receptor NKp30 has been shown in NK cells from elderly donors [32, 57, 58]. NKp30 also plays an important regulatory role mediating the cross talk between NK and DCs via the recognition of an unknown ligand expressed on DCs. The engagement of the NKp30 receptor can lead either to a direct killing of DCs by NK cells or to the secretion of IFN- γ and TNF- α and the subsequent maturation of DCs. Therefore, NK-activated DCs loaded with tumor or virally derived antigen have an increased capacity to prime T cells. In return, activated DCs release Th1 cytokines that further enhance NK activation [59, 60]. The decreased expression of NKp30 on NK cells from elderly individuals should also affect the interaction between these cells leading to a decreased capacity to collaborate in the initiation of the adaptive immune response against virus-infected or tumor cells.

Effect of Aging on NK Cell Response to Cytokines

Cytokine activation of NK cells results in proliferation, enhanced cytotoxicity, and the synthesis and release of cytokines and chemokines. While IL-2-induced NK cell proliferation is decreased in old donors [29], the enhancement of the cytotoxic activity of NK cells in response to IL-2, IL-12, or IFN- α and IFN- γ is well preserved in the healthy elderly [32, 61–63]. The production

of IFN- γ by NK cells after activation is also maintained in the elderly [32], with a increased production of IFN- γ by CD56^{bright} cells, potentially representing a compensatory augmentation of cytokine production to maintain the important immunoregulatory role of these cells in older individuals [55]. However, a marked early decrease in IFN- γ secretion in response to IL-2, which can be overcome by increasing the incubation time, has also been shown [63]. The production of chemokines by NK cells is decreased in old subjects in response to IL-2 or IL-12 [64–66]. Considering that CD56^{dim} NK cells can produce high amounts of IFN- γ , and whereas chemokines are mainly produced by CD56^{bright} NK cells, the decrease in this subset in the elderly can explain their decreased production by NK cells associated with aging. Because of the costimulatory role of chemokines in NK responses, the decreased production of chemokines can be involved in the defective functional activity of NK cells from old subjects.

Concluding Remarks

NK cells are cytotoxic lymphocytes involved in the early defense against virus-infected and tumor cells. Besides their cytotoxic capacity, NK cells also regulate the immune response by producing cytokines and chemokines that directly participate in the elimination of pathogens or activate other cellular components of immunity. The NK cell frequency and absolute value tend to increase with age. In very healthy elderly, including centenarians, NK cell numbers and functions are well preserved, whereas decreased NK cell activity is associated with an increased incidence of infectious and inflammatory diseases. Several alterations have been described in human NK cells with advancing age, thus contributing to age-associated deterioration of the immune response. The results summarized in this work support the notion that aging leads to a redistribution of NK cell subsets with a decrease in CD56^{bright} cells and an expansion of the CD56^{dim} subset, in particular highly differentiated CD56^{dim} CD57+ NK cells. Age-associated NK cell remodeling can explain many of the phenotypic and functional changes in NK cells associated with healthy aging.

Further studies on the effect of aging on all NK cell subsets and on the expression and function of activating and inhibitory receptors, as well as a more profound study of the molecular mechanisms involved in these processes, are required to better understand age-associ-

ated NK cell alterations. Considering the increasing advances in the understanding of the mechanisms involved in NK cell interactions not only with tumor- and virus-infected target cells but also with other cells of the immune system, it is of high interest to analyze the contribution of NK cell aging to the process of immunosenescence.
