Abstract

Since the initial report that clearly established a causal role between duplication of the *MECP2* gene and a severe syndromic form of intellectual disability, many new patients have been identified and reported, and the etiology in already published families solved. This has led to the establishment of a clinically recognizable disorder. Here, we review the clinical data of 129 reported and nonreported male patients with *MECP2* duplication syndrome.

History

The advent of array-based comparative genomic hybridization has contributed significantly to the field of intellectual disability (ID). Not only are new syndromes and genes being identified at a rapid pace, but also new genetic mechanisms leading to disease are being unraveled. The identification of duplications involving the

MECP2 gene and hence increased *MECP2* protein dosage as causal for a severe syndromic form of ID in males was at first surprising [Van Esch et al., 2005]. Until then, *MECP2* was considered an almost exclusive female topic. However, fundamental studies in mice had already shown that overexpression of mouse and also human protein resulted in a progressive neurological disorder [Collins et al., 2004; Luikenhuis et al., 2004] and it had been hypothesized that *MECP2* overexpression could lead to a post-natal neurological phenotype in human [Collins et al., 2004].

Since the initial report that clearly established a causal role between duplication of the *MECP2* gene and a severe syndromic form of ID, many new patients have been identified and reported, and the etiology in already published families solved [Lubs et al., 1999; Meins et al., 2005; Van Esch et al., 2005; del Gaudio et al., 2006; Friez et al., 2006; Bauters et al., 2008; Smyk et al., 2008; Clayton-Smith et al., 2009; Echenne et al., 2009; Kirk et al., 2009; Lugtenberg et al., 2009; Prescott et al., 2009; Velinov et al., 2009; Bartsch et al., 2010; Belligni et al., 2010; Fernandez et al., 2010; Ramocki et al., 2010; Reardon et al., 2010]. The comparison of all these reported male patients enabled the establishment of a clinically recognizable disorder (table 1).

Clinical Features

In table 1, the clinical features and their incidence are listed, based on the review of the literature combined with clinical data on 15 nonreported patients known to the author. These numbers are far from complete and depend on the completeness of the reports and, more importantly, on the age of the patients at the time of description, especially since some of the clinical features change with age.

The cardinal features of the *MECP2* duplication syndrome include early infantile hypotonia, delayed psychomotor development resulting in severe to profound ID with absent to very limited speech and neurological symptoms, including abnormal gait, epilepsy and spasticity. In the majority of patients, recurrent infections, especially of the respiratory tract occur, and often gastrointestinal motility problems are present. In those patients who underwent brain imaging, 3 in 4 were reported to have structural and even progressive anomalies. Dysmorphism is common and some facial features are shared by several patients.

Psychomotor Development

During the first weeks of life, feeding difficulties resulting from hypotonia may become evident in affected males. The child is floppy and may also exhibit difficulty with swallowing, gastro-esophageal reflux, failure-to-thrive, and extensive drooling, sometimes necessitating nasogastric tube feeding.

As a result of the axial hypotonia, motor developmental milestones including sitting and crawling are delayed in almost all patients. Hence, walking is also severely delayed (range 18 months–4 years) but 3 in 4 males ultimately achieve ambulation without support; however, gait is often ataxic and several affected boys develop a compensating lumbar hyperlordosis. However, with increasing age, many patients manifest a neurological and general regression that will ultimately result in loss of ambulation. The same holds true for speech development. The majority of affected individuals (~80%) do not develop speech. In some individuals who were able to speak a few single words in early childhood, speech was progressively lost in adolescence. Recurrent infections and refractory epilepsy may be contributing factors to regression, but the true physiologic/molecular cause remains unclear. Further fundamental studies are necessary to elucidate the effect of increased *MECP2* dosage on the human brain. In addition, we cannot exclude a possible influence of increased gene dosage of other genes

within the respective duplicated regions. Most affected males function at the level of moderate to severe ID and require lifelong specialized care.

Neurological Symptoms and Behavior

In 75% of affected males, the early hypotonia gives way to spasticity in childhood. However, the first pyramidal signs may already appear during the first years of life. The spasticity is more pronounced in the lower limbs and mild to severe contractures of hips, knees and ankles may develop over time. Often the use of a wheelchair becomes necessary in early adulthood. In some patients, the use of botulinum toxin A injections can be considered. Importantly, this should happen on an individual basis, within an expert multidisciplinary clinical setting with the necessary physiotherapeutic support. Botox infiltrations might be beneficial to keep the patient ambulatory and to prevent joint dislocations, especially of the hips.

Seizures are seen in 54% of individuals. Age of seizure-onset is very variable and in some patients they only appeared during the second decade of life, so 54% may be an underestimate. Generalized tonic-clonic seizures are most often observed, but atonic seizures, absences and also myoclonic seizures have been described. In some individuals, seizures were very refractory to treatment and it is often noted that the onset and the severity of the seizures correlate with neurological deterioration, characterized by loss of speech, hand use, and/or ambulation. Echenne et al. [2009] reported the electroencephalographic findings in 5 of their affected patients who exhibited myoclonic-astatic seizures. These electroencephalograms showed unusual, very slow background activity and multifocal theta or delta waves associated with focal or generalized spike-waves, instead of the expected rapid rhythm and poly-spike waves. This slow background activity was also seen in the patients reported by Ramocki et al. [2010], and in several of our unreported patients.

In some patients, autistic features, stereotypic behavior or mood disorders were observed [Meins et al., 2005; del Gaudio et al., 2006]. Ramocki et al. [2010] reported abnormal movements in 9 patients, including choreiform movements of the upper limbs and hands and also of the head and tongue. In addition, they observed stereotypic midline hand movements. This was also present in the patient reported by Meins et al. [2005].

Neuroradiology

In the majority of patients with a *MECP2* duplication who underwent brain imaging, neuroradiological abnormalities were present. Although the presentation of these

data are not very consistent, some characteristics are emerging, including generalized ventricular dilatation, cortical atrophy, hypoplasia of the corpus callosum and increased signal in the periventricular white matter, especially in the posterior regions of the brain (table 1). It is very possible that some of these abnormalities are secondary to the long-standing and frequent seizures some of these patients experience. Interesting, however, is the report by Reardon et al. [2010] that describes a progressive neuroradiological phenotype in patients with *MECP2* duplications. These authors present successive neuroradiological images over several years in 3 patients, showing progressive cerebellar degenerative changes, even in an affected male who did not experience seizures. Therefore, it was postulated that these progressive changes are directly related to the duplication, rather than to a sec-

ondary seizure-related event. Unfortunately, consecutive neuroradiological studies are rare in the severely affected patients older than 10 years of age.

Recurrent Infections

Recurrent infections, especially of the respiratory tract and often requiring hospitalization, intravenous antibiotics therapy and even assisted ventilation, occur in 70% of affected individuals. In a minority of patients, a tracheostomy is required. Other types of infections, such as meningitis and urinary tract infections have also been described. These recurrent infections may lead to further deterioration of the general and neurological status, and in some patients they can be fatal. Together with the refractory epilepsy and the neurological deterioration, these infections are responsible for the early death report-

ed in many individuals, the diagnosis often being made retrospectively. It is difficult to give a precise number on early deaths before the age of 25 years, because many of the recently published patients are still young and were diagnosed early. Therefore, the statistical percentage of 39% is likely an underestimate.

The *IRAK1* gene maps between *LICAM* and *MECP2* and is duplicated in almost all patients reported to date. This gene encodes an interleukin receptor-associated kinase involved in the toll-like receptor transduction pathway, a pathway that is important for immunity against certain pyogenic bacteria. By means of their kinase and adaptor functions, IRAKs initiate a cascade of signaling events eventually leading to induction of inflammatory target gene expression. Interestingly, we and others have found that affected boys do not respond adequately to

vaccines containing polysaccharide antigens (e.g. *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, *Neisseria meningitidis*) and often require extra boosters [Friez et al., 2006; Prescott et al., 2009]. The same authors also performed immunological laboratory investigations, including T- and B-cell numbers, T-cell functional studies, serum immunoglobulin levels (IgM, IgE, IgA, IgD and IgG plus subclasses) and complement activity, but could not detect consistent abnormalities that could explain the occurrence of the recurrent infections [Friez et al., 2006; Prescott et al., 2009]. In addition, we specifically challenged the IRAK1 pathway in 3 affected patients and 5 age-matched controls. Fresh blood lymphocytes were stimulated by ionomycin (PMA-IONO), recombinant human IL1 beta or heat-killed *S. pneumoniae* serotype 3 and subsequently, TNF and IL-8 production was

measured. We did not, however, see any differences in cytokine production between affected and controls (results not shown). Taken together, the effect of duplication of *IRAK1* in humans, and its role in the observed immunological problems present in many *MECP2* duplication patients is far from clear. It is possible that other duplicated gene(s) or even disruption of regulatory elements nearby contribute to the immune system dysfunction. Our experience is that, provided the first severe infections are well managed, this proneness to infections has the tendency to improve spontaneously with increasing age. Nevertheless, infections should be treated aggressively and appropriately.

Gastrointestinal Problems

Gastrointestinal problems have often been reported in individuals with Xq28 duplications. Gastro-oesophageal reflux and swallowing dysfunction are frequent in the hypotonic affected infant and may contribute to the recurrent respiratory infections during the first years of life. In some patients, fundoplication or permanent gastrostomy clearly improved the respiratory distress and their general feeding condition.

Clinically important constipation is reported in more than one third of the patients. Constipation is in general a frequent problem in the large group of patients with severe mental and motor problems. However, the report by Clayton-Smith et al. [2009] is interesting as they describe several patients with Xq28 duplications who suffered from chronic intestinal pseudo-obstruction, a serious gastrointestinal dysmotility syndrome, and bladder dysfunction. Hirschsprung disease (HSCR) was ruled out in some of them. The authors state that duplication of the *FLNA* gene, localized telomeric to *MECP2*, may well be responsible for the intestinal pseudo-obstruction in these patients. This is further corroborated by previous reports of *FLNA* mutations in X-linked families with intestinal pseudo-obstruction [Hehr et al., 2006; Gargiulo et al., 2007]. Although not all patients with an *FLNA* duplication suffer from constipation, this observation has raised awareness for this particular symptom.

Dysmorphism

In young patients, a hypotonic face with tented upper lip, open mouth and often excessive drooling is present. In older patients, additional facial features become more recognizable. Many patients have, in addition to the facial hypotonia, deep-set eyes, a narrow nose, prominent chin, and large ears [Clayton-Smith et al., 2009].

Growth parameters, in particular head circumference, are generally within the normal range, in contrast to the microcephaly observed in the classical Rett syndrome. However, due to the prolonged hypotonia, the skull shape is often asymmetric.

Other Reported Features

In a recent report, Fernandez et al. [2010] reported a patient with HSCR and a duplication of the Xq28 region including *MECP2* (~300 kb). The authors excluded mutations in *RET* and 6 other HSCR-related genes as causal for the HSCR, and suggested that the enteric phenotype could be due to increased dosage of *LICAM* in combination with additional molecular events not yet identified. This hypothesis is supported by the fact that mutations in *LICAM* have been found in patients who present with X-linked hydrocephalus and HSCR.

Interestingly, another neurocristopathy, namely congenital central hypoventilation syndrome was reported in another patient with a small *MECP2* duplication [Belligni et al., 2010]. Pathogenic mutations in *PHOX2B* and *RET* were excluded. This child also suffered from severe constipation, but HSCR was excluded by rectal biopsy. It will be of interest to see whether these patients represent unique cases or whether neurocristopathies can be considered as part of the syndrome, especially in patients with increased dosage of *LICAM*.

Carrier Females

Most *MECP2* duplications identified in males are inherited from a carrier mother, who is asymptomatic, because of extreme (>90%) to complete skewing of X chromosome inactivation with the duplication-bearing X chromosome being preferentially inactivated [Van Esch et al., 2005]. One study reported neuropsychiatric symptoms, including depression, anxiety and autistic features, in female carriers who have normal intellectual abilities [Ramocki et al., 2009].

More recent reports, however, also describe mildly affected female carriers who do not show complete skewing. Reardon et al. [2010] reported a mildly affected sister of an affected boy, with X-inactivation ratio (XCI) of 30/70 in blood. Kirk et al. [2009] found a different XC ratio in hair roots (26/74) than in peripheral blood (100/0) in a mildly affected mother. Hence, it seems that 70% skewing or less is sufficient to cause mild learning problems in females. But more importantly, these findings complicate genetic and prenatal counseling, and more detailed and larger studies on female carriers are mandatory.

Fig. 1. Upper panel: male patient with *MECP2* duplication at age 2 (left) and age 5 (right). Note the hypotonic face with tented upper lip, open mouth and excessive drooling as well as the deep-set eyes and narrow nose. Lower panel: 15-year-old boy who regressed after onset of severe therapy-resistant epilepsy. Note the coarse hypotonic face and malformed nose due to the frequent drop attacks and chronic nasogastric tube feeding.

In contrast to the familial female cases, *de novo* duplications involving *MECP2* resulting in a clinical phenotype have also been reported in females. In the majority of cases, the females are symptomatic because the duplicated region is functionally active due to translocation to an autosome. In these situations, a phenotype as severe as in males is present [Lachlan et al., 2004; Sanlaville et al., 2005; Auber et al., 2010; Makrythanasis et al., 2010]. In addition, Grasshoff et al. [2011] reported on 2 female patients with a *de novo* submicroscopic *MECP2* duplication that occurred on the paternal allele. These 2 females presented with unspecific mild-to-moderate ID, autistic features, and recurrent infections in early childhood, constipation and late-onset neurological features in 1 of them. Both females had random XCI. These authors propose that *de novo* occurrence of the *MECP2* duplication might have an effect on the XCI by preventing a protec-

tive ‘mutation-induced’ skewed XCI by a yet unrecognized mechanism. This would mean that there could be a different trigger for the methylation process from an inherited *MECP2* duplication than from the one that occurred *de novo*. Another possible explanation may be a postzygotic mosaic occurrence of the duplication, but the authors could not find clinical or molecular evidence for this mechanism [Grasshoff et al., 2011].

Genotype-Phenotype Correlation

To date, more than 110 patients have been reported, nearly all with different duplication sizes and breakpoints, and it is indisputable that increased dosage of *MECP2* is sufficient to cause the core phenotype (table 1). The smallest duplication, identified by several authors, only contains the *IRAK1* and *MECP2* genes and were found in affected males who presented with developmental delay, epilepsy, spasticity and recurrent lung infections [del Gaudio et al., 2006; Bauters et al., 2008; Lugtenberg et al., 2009]. Many authors have tried to further dissect the different Xq28 duplications in order to identify genes that contribute to the clinical spectrum. The potential involvement of *IRAK1*, *LICAM*, and *FLNA* has been discussed above. We cannot exclude that other (ID) genes within the duplicated region exert an additive effect. In this regard, we recently identified several families with ID, carrying duplications of the Xq28 region, not involving *MECP2* [Vandewalle et al., 2009]. Interestingly, also patients with a triplication of *MECP2* have been identified. These patients exhibited a very poor development, showing that *MECP2* dosage apparently correlates with severity [del Gaudio et al., 2006].

Besides the submicroscopic rearrangements involving *MECP2*, which are the focus of this review, also larger, cytogenetically visible rearrangements involving Xq28 and *MECP2* in particular have been reported [Lachlan et al., 2004; Sanlaville et al., 2005]. About 40 cases of Xq28 functional disomy due to cytogenetically visible rearrangements have been described and in the majority of them, an unbalanced X/Y or X/autosome translocation underlies the functional disomy. Rearrangement sizes are much larger and vary between 8 and 23 Mb, often also comprising cytogenetic band Xq27. As expected, the clinical phenotype in these patients is severe and largely overlaps with the phenotype associated with the microscopic duplications involving *MECP2*. However, in these patients additional clinical features are often present, like pre- and postnatal growth deficiency, inguinal hernia and palatal and genital anomalies. This indicates that

there are other genes in the large duplicated region that are dosage sensitive and exert an effect.

These large cytogenetically visible duplications have also been found in severely affected females with a functional Xq28 duplication without skewing of X chromosome inactivation. In most of these females, the duplication arises from an unbalanced X-autosomal translocation or a genomic insertion elsewhere in the genome, explaining the absence of skewing of the aberrant X chromosome [Lachlan et al., 2004; Sanlaville et al., 2005; Makrythanasis et al., 2010].

Incidence

The overall prevalence of this condition is estimated to be 1% of unexplained X-linked ID [Lugtenberg et al., 2009]. In 2 separate studies, duplications were found in 1.6–2.2% of male patients, specifically referred for *MECP2* molecular analysis [del Gaudio et al., 2006; Lugtenberg et al., 2009]. The more stringent the inclusion criteria are (core features, linkage to Xq28), the higher is the likelihood of identifying a *MECP2* duplication, with estimates as high as 15% [Van Esch et al., 2005; Ramocki et al., 2010].

To date, all reported microduplications in males were inherited from a carrier mother except one. However, this de novo microduplication of 2.15 Mb was reported in a patient with a de novo Xq/Yq translocation [Velinov et al., 2009].

Management

Patients with *MECP2* duplication syndrome manifest many different problems, necessitating a lifelong multidisciplinary approach. From infant age on, feeding and swallowing problems should be monitored to prevent aspiration pneumonia, optimize the general condition and prevent malnutrition of the child. Removal of adenoids can be beneficial for those children who manifest obstructive sleep and upper airway obstruction. However, good clinical indications should still drive the decision to pursue surgical intervention, and every child needs a tailored approach.

Given the many neurological problems, evaluation, treatment and follow-up by a pediatric neurologist and rehabilitation specialist are essential. Developmental stimulation including physiotherapy, speech and communication therapy is extremely important and should

be adapted to the individual needs of the patients. Also, the spasticity should be monitored to prevent secondary contractures, and in some patients the use of botulinum toxin can be considered. However, this has to be performed in an expert multidisciplinary clinical setting with the necessary physiotherapeutic support, weighing advantages and disadvantages for each individual patient.

Diagnosis of type and frequency of seizures should be done by clinical history and electroencephalogram. If seizures are present, they usually respond well to standard therapy with anti-epileptic drugs; however, a subset of affected males experience treatment refractory seizures, and in this group neurological deterioration and regression often occurs.

Given the predisposition to infections, especially of the respiratory tract, they should be treated immediately and aggressively with appropriate antibiotics. Often hospitalization and even assisted ventilation is necessary. There is much debate about the use of prophylactic antibiotics in children with the *MECP2* duplication. Given the low immunological response to vaccines containing polysaccharide antigens, administration of a booster might be considered.

Molecular Genetics and Diagnosis

Most patients have been identified by array comparative genome hybridization technologies, since this technique has become the standard in the diagnostic work-up of patients with developmental delay. Other quantitative methods such as quantitative real-time PCR or MLPA can also be used for direct clinical testing or confirmation of array results.

The sizes of the reported duplications vary between 300 kb and 4.2 Mb, and are too small to be detected by classical chromosome analysis. This is in contrast to the larger, cytogenetically visible duplications of the Xq28 region that also involve *MECP2*, discussed in the Genotype-Phenotype Correlation section.

Several groups already reported Xq28 as a region at high risk for genomic instability [Aradhya et al., 2002; Sanlaville et al., 2005]. The *MECP2* duplications are non-recurrent with unique duplication sizes and breakpoints. Two groups studied the underlying mechanism(s). They both showed that, even though some breakpoint regions coincide with low copy repeats, none of the duplications appear to be the result of nonallelic homologous recombination [Bauters et al., 2008; Carvalho et al., 2009].

Moreover, some of the duplications are much more complex than previously thought: both groups found stretches of nonduplicated sequences within the duplicated region, and in some patients the duplication contained an embedded triplicated segment. Both nonhomologous end joining followed by break-induced repair as well as fork stalling and template switching were proposed as mechanisms that could explain these rearrangements [Bauters et al., 2008; Carvalho et al., 2009].

Future Perspectives

The report of more than 100 patients with duplication of the *MECP2* gene has now permitted the delineation of a clinical recognizable ID syndrome. Therefore, copy number testing for *MECP2* should be included in the diagnostic workup of all male patients with moderate to severe ID and neurological symptoms. Molecular karyotyping is currently the standard diagnostic test because it

also provides data on size and gene content of the Xq28 rearrangement. To date, there exists no cure and individuals with *MECP2* duplication syndrome require lifelong multidisciplinary care to maximize function and prevent regression. The ongoing fundamental research in the field of *MECP2* and its related disorders will give insights into the molecular and cellular functioning of this protein, which is crucial for normal human brain functioning and development. Better understanding of the disease will ultimately lead to the identification of targets and pathways for therapies to improve or cure the symptoms.

Acknowledgements

We are thankful to Dr. T. de Ravel for critical reading of the manuscript. We are grateful to all the patients, their families and caregivers who were willing to share their invaluable contribution, experience and insight into the disorder. H. Van Esch is clinical investigator at F.W.O. Vlaanderen.
