Key Words

Sleeve gastrectomy · Nasogastric tube · Complication

Abstract

Bariatric surgery has become an integral part of morbid obesity treatment with well-defined indications. Some complications, specific or not, due to laparoscopic sleeve gastrectomy (LSG) procedure have recently been described. We report a rare complication unpublished to date: a nasogastric section during great gastric curve stapling. A 44-year-old woman suffered of severe obesity (BMI 36.6 kg/m²) with failure of medical treatments for years. According to already published technique, a LSG was performed. Six hours postoperatively, a nurse removed the nasogastric tube according to the local protocol and the nasogastric tube was abnormally short, with staples at its extremity. Surgery was performed with peroperative endoscopy. In conclusion, this is the first publication of a nasogastric section during LSG. Therefore we report this case and propose a solution to prevent its occurrence. To avoid this kind of accident, we now systematically insert the nasogastric tube by mouth through a Guedel cannula. Then, to insert the calibrating bougie, we entirely withdraw the nasogastric tube.

Introduction

Bariatric surgery has become an integral part of morbid obesity treatment with well-defined indications [1–4]. It even appears as the sole treatment for long-term weight loss stability and regression of morbidities [5–11]. Two types of bariatric surgery are available: restrictive (laparoscopic adjustable gastric banding and laparoscopic sleeve gastrectomy) and malabsorptive (laparoscopic gastric bypass) procedures. Laparoscopic

sleeve gastrectomy (LSG) is increasingly being recognised as a valid stand-alone procedure for the surgical management of morbid obesity. LSG is becoming more and more popular because this technique is more comfortable and more efficient than laparoscopic adjustable gastric banding and causes less morbidity than bypass. During this intervention, two different tubes are used by the anaesthesiologists and introduced through the nose: a nasogastric tube and a calibration silastic tube. The calibration silastic tube, allowing the gastric section, is a full tube and is interesting for avoiding stapling of this tube or narrowing of the stomach tubulisation.

Some complications due to LSG procedure, specific or not, have recently been described [12, 13]. We report a rare complication unpublished to date: a nasogastric section during great gastric curve stapling.

Case Report

A 44-year-old woman suffered from severe obesity (BMI 36.6 kg/m², weight 88 kg, height 155 cm) with failure of medical treatments for years. Her obesity was accompanied by comorbidities, including diabetes mellitus type 2 and metabolic syndrome NCEP-ATP3 [14]. She was thus eligible for bariatric surgery according to the HAS (Haute Autorité de la Santé) guidelines [5]. After a multidisciplinary consulting meeting, we decided to perform a LSG.

The gastric sleeve is created by using a linear stapler. According to already published technique [13–15], the staples are applied alongside a 34-Fr calibrating bougie positioned against the lesser gastric curve. The anaesthesiology team helps to correctly set up the bougie. Before the insertion of the calibrating bougie, the pernasal nasogastric tube is partially removed (20 cm) from the stomach and positioned in the cavum. Once the bougie is withdrawn, a leak test is performed using intraoperative methylene blue dye through a pernasal nasogastric tube repositioned in the stomach.

Six hours postoperatively, when the patient had come back to the recovery room, the nurse removed the nasogastric tube according to the local protocol. In this case, the nasogastric tube was abnormally short and staples were present at its extremity (fig. 1). The surgeons were informed of this situation. The patient did not present hyperthermia (37.7°C), tachycardia (87 bpm), abdominal pain (under analgesic drugs) or dyspnoea, but she presented nausea according to the normal postoperative course. Peritoneal syndrome was not present at abdominal palpation. No biologic inflammatory syndrome was found.

After discussion we decided, with the patient's information, to perform an abdominal CT scan. Tomographic imaging showed a nasogastric tube fragment in the antrum (fig. 2). We performed a surgical laparoscopic revision in association with gastric endoscopy. There were no staple line leaks. The abdominal exploration did not find any haematoma or abdominal effusion. The fragment of the nasogastric tube was localised endoscopically. This fragment was incarcerated in the staple line, and endoscopic extraction (fig. 3) created a staple line defect. The gastric wall was subsequently repaired by the surgeon and the methylene blue test was negative for staple line leak.

Discussion

LSG has recently emerged as a reproducible surgical technique effective for long-term weight loss stability with regression of most major associated comorbidities, such as diabetes type 2. Mortality is lower than 1%. Complications caused by this surgical technique vary from 0 to 10%, with a median estimate of 5.1%, according to studies. The major complication, by its frequency and its consequences, is gastric fistula, blind or draining into a nearby organ. This fistula is most often located at the upper end of the stapling line [13]. To our knowledge, this is the first publication of nasogastric

section during LSG. Therefore we report this case and propose a solution to prevent its occurrence.

During LSG, the nasogastric tube is pernasally inserted and is not entirely removed during gastric section. Its extremity stays in the cavum and the calibrating bougie is introduced through the mouth. Therefore, in this case the calibrating bougie led the nasogastric tube to the stomach. To avoid this kind of accident, we now systematically insert the nasogastric tube by mouth through a Guedel cannula. To insert the calibrating bougie we must entirely withdraw the nasogastric tube.

When this situation occurs, surgery must be systematically associated with endoscopic removal of the remnant nasogastric tube: indeed, its ablation can create a staple line defect. The gastric wall is subsequently repaired by the surgeon and the methylene blue test is systematically performed in order to prevent staple line leak.

Fig. 1. In the recovery room, the nurse observes that the nasogastric tube was shorter, with staples fixed on its extremity (☆).

Fig. 2. Tomographic imaging with 3D reconstruction. The remnant nasogastric fragment (☆) is located in the antrum, and the abdominal drain (△) against the gastric staple line.

Fig. 3. Endoscopic extraction of the remnant nasogastric tube. The remnant fragment of the nasogastric tube (☆) is localised endoscopically and extracted with an endoscopic loop (△). This approach is completed by the surgeon, who performs laparoscopic suturing of the staple line defect.
