Abstract

Background: Compounds which activate the innate immune system, such as lipopolysaccharide, are significant components of ambient air, and extremely difficult to remove from the environment. It is currently unclear how prior inhalation of endotoxin affects allergen sensitization. We examined whether lung-specific endotoxin tolerance induction prior to sensitization can modulate the response to allergen. **Methods:** Endotoxin tolerance was induced by repeated intratracheal exposure to endotoxin. All mice were then sensitized and challenged by direct intratracheal instillation of cockroach allergen. **Results:** After allergen sensitization and challenge, endotoxin tolerant mice had significantly decreased airways hyperresponsiveness to methacholine challenge, which was confirmed by invasive lung function tests. Decreased goblet cell hyperplasia and mucus production were also found by histological assessment. Tolerant mice were protected from airway eosinophilia through the mechanism of reduced CCL11 and CCL24. Interestingly, endotoxin tolerant mice had only a modest reduction in

cockroach-specific IgE; however, total IgE was significantly reduced. **Conclusions:** These data show that induction of endotoxin tolerance prior to sensitization protects against the hallmark features of asthma-like inflammation, and that transient modulation of innate immunity can have long-lasting effects on adaptive responses.

Introduction

Asthma is a chronic inflammatory disease characterized by three hallmark features: bronchial hyperresponsiveness, airway eosinophilia and IgE production [1]. It is also widely understood that innate immune activating factors, particularly signaling through the Toll-like receptor (TLR) ligands, influence asthma severity [2]. Inhalation of high-dose lipopolysaccharide (LPS), concomitant with allergen sensitization has been shown to protect against the development of allergy [3]. While the exact mechanisms dictating this immune modulation are not known, it is generally accepted that the role LPS plays in asthma severity depends on the dose and timing of exposure [4]. This is further highlighted by the hygiene hypothesis, which asserts that early exposure to

high levels of innate immune activating compounds can protect against the onset of atopy, while lack of exposure can increase the risk of developing allergic diseases [5, 6]. This has been postulated as an underlying cause for increased asthma incidence and severity in developed countries. Additionally, the incidence and severity of asthma in inner city children is far greater than that seen in children raised in farming environments, and the levels of LPS present in farm environments are significantly higher than those measured in inner city homes [7, 8]. We sought to investigate pulmonary LPS tolerance as a mechanism responsible for attenuated asthma severity in response to cockroach allergen (CRA) sensitization and challenge.

Repeated exposure to LPS can induce a transitory state of LPS hyporesponsiveness [9]. This phenomenon has recently been identified as a unique mechanism by which the lung protects itself from excessive inflammation, by attenuating TNF α , and CXC chemokine production, while maintaining the capacity to recruit neutrophils and thus fight bacterial challenge [10, 11]. In this study, we employed a novel model combining LPS tolerance and asthma induction to determine how repeated LPS inhalation affects the adaptive response. We used a clinically relevant model of intratracheal allergen sensitization without the use of adjuvants. Given the ubiquitous presence of LPS in the environment, understanding its role in the onset and progression of allergic diseases is essential in determining effective treatment methods.

Materials and Methods

Animals

Female BALB/c mice, 9–12 weeks old, were purchased from Jackson Laboratories (Bar Harbor, Me., USA), and maintained under standard laboratory conditions. The mice were housed in a temperature- and humidity-controlled room with 12-hour light/dark cycles and were allowed food and water *ad libitum*. All experiments were performed according to the National Institutes of Health guidelines and were approved by the Boston University Institutional Animal Care and Use Committee.

Induction of LPS Tolerance and Asthma-Like Pulmonary Inflammation

LPS tolerance was induced by exposing mice to 1 μ g LPS (*E. coli* LPS O111:B4, Sigma-Aldrich-62325) in a total volume of 50 μ l sterile PBS once daily during days –4 to –1, by direct intratracheal instillation, as previously described. Nontolerant mice received 50 μ l sterile PBS [12]. On day 0, all mice were sensitized to cockroach allergen (CRA) by intratracheal administration of 2 μ g CRA (Greer Laboratories, LeNoir, NC, Item # B46) in 50 μ l PBS. No adjuvants were used for asthma induction. On day 14, mice

were challenged intratracheally with 1 μ g CRA, and received the same challenge on day 21. This CRA preparation contained 200 ng LPS contamination for sensitization and 100 ng LPS at challenge as determined by *Limulus* amoebocyte lysate assay [10]. Airways hyperresponsiveness and airway resistance were measured and animals were sacrificed at various timepoints as indicated in the figure legends. The 0 h timepoint represents sacrifice immediately prior to receiving the day 21 CRA challenge.

Airways Hyperresponsiveness

Airways hyperresponsiveness was measured using unrestrained whole-body plethysmography (Buxco Systems, Troy, N.Y., USA). Mice were placed in the instrument chamber and allowed to acclimate for 5 min and baseline measurements were then recorded for 5 min. Next, mice were challenged for 2 min with aerosolized PBS, followed by increasing doses of methacholine (Sigma, St. Louis, Mo., USA). Each aerosol was followed immediately by 5 min of data collection. The partial pressure difference between the experimental and a reference chamber is represented as the PenH parameter. This has been shown to correlate closely with invasive measurements, and has been used in several high-impact publications [13–15]. The data is represented as the percent increase in PenH above baseline.

Airway Resistance

Whole-body plethysmography data were further verified using invasive pulmonary function tests. For measurement of mouse airway resistance, mice were anesthetized with an i.p. injection of 1:5 diluted pentobarbital (Nembutal®, 0.016 ml/g body weight, Ovation Pharmaceutical, Deerfield, Ill., USA). The paralytic was pancuronium (Sigma-Aldrich, St. Louis, Mo., USA) at 0.5 μ g/g body weight. Adequate surgical sedation was determined by a firm squeeze of the foot pad. A tracheotomy was then performed by insertion of an 18-gauge polyethylene cannula into the distal trachea. The mouse was placed on the FlexiVent mechanical ventilator (Scireq Scientific Respiratory Equipment, Montreal, Canada) and ventilated at 190 breaths per minute with positive end-expiratory pressure set at 3 cm H₂O. Airway resistance measurements in response to increasing concentrations of aerosolized methacholine were obtained through periodic computer-generated ‘snapshot 150’ forced-maneuver interruptions in ventilation. Data are presented as resistance change from baseline (cm H₂O per milliliter per second).

Bronchoalveolar Lavage and Lung Homogenate Preparation

Mice were exsanguinated and bronchoalveolar lavage (BAL) was performed by cannulating the trachea. The lung was lavaged with two 1-ml aliquots of warm Hanks’ balanced salt solution (HBSS, Gibco, Grand Island, N.Y., USA). Both aliquots were centrifuged and the supernatant of the first wash was removed and frozen at –20°C for cytokine analysis. The supernatant from the second wash was discarded and the cell pellets from both aliquots were combined. Total cell counts were obtained using a Beckman-Coulter particle counter model ZF (Coulter Electronics Inc., Hialeah, Fla., USA). Cytospin preparations were stained with Diff-Quick and 300 cell differential counts were performed to determine the absolute numbers of inflammatory cells. The right lung was removed, placed in ice-cold protease inhibitor cocktail (Roche, Indianapolis, Ind., USA) containing 0.00005% Triton X-100 in PBS, and homogenized with three 10-second passes in a

Brinkmann Polytron PT3000 homogenizer. An aliquot was removed and sonicated in 0.5% cetyltrimethylammoniumchloride (CTAC) (Sigma) for eosinophil-specific peroxidase assay [16]. The homogenized and sonicated mixtures were centrifuged at 15,000 g for 15 min. The homogenate supernatant was removed and stored at -20°C for cytokine analysis and the supernatant from the sonicated fractions was used immediately for peroxidase assay.

Eosinophil Peroxidase Assay

Eosinophil peroxidase (EPO) assay was performed as described previously, with some modifications [16]. Supernatants of the mixture sonicated in CTAC were diluted 1:3 in 10 mM HEPES, pH 8, in quadruplicate in a 96-well plate. 150 μl ice-cold stop solution (4 N H_2SO_4 + 2 mM resorcinol) was added to two of the sample wells. 75 μl substrate solution containing 6 mM KBr, 1.5 mM *o*-phenylenediamine (Sigma, St. Louis, Mo., USA, P9029), and 0.3% H_2O_2 in 50 mM HEPES, pH 8, was added to the two remaining sample wells. The reaction was incubated in the dark for 30 s. 150 μl ice-cold stop solution was added and the absorbance was read at 490 nm.

ELISA

Cytokines, chemokines and antibodies were measured by sandwich ELISA as previously described [17]. Antibody pairs and recombinant standards were purchased from R&D Systems (Minneapolis, Minn., USA). 20% normal lung homogenate was added to the standards when assaying lung homogenate samples to adjust for increased background caused by nonspecific matrix effects. ELISAs for measuring antibodies were performed by the same standard protocols with reagents purchased from Bethyl Laboratories (Montgomery, Tex., USA). Cockroach allergen ELISAs were performed as previously described with antibody pairs and recombinant standards from Indoor Biotechnologies (Charlottesville, Va., USA) [18].

Cysteinyl-Leukotriene Immunoassay

Cysteinyl leukotriene levels in the BAL fluid were measured by a commercially available Enzyme-linked Immunoassay Kit (Cayman Chemicals, Ann Arbor, Mich., USA) according to the manufacturer's instructions. All samples were run at two dilutions, and only %B/B₀ values in the linear range of the standard were accepted. %B/B₀ values falling out of this range were rerun at an appropriate dilution.

Histopathology

Immediately after collection of the left lung, the right lung was harvested, fixed in 70% ethanol, paraffin embedded and processed for routine histology. Separate sections were also stained with periodic acid-Schiff reagent and were examined under a light microscope [19]. Digital images of the entire section were taken and analyzed using NIH ImageJ Software. The outline of each figure was traced and the total area in pixels was calculated using the measure function. Positive PAS staining was selected using the Color Deconvolution plug-in. The area of positive staining was measured using the measure feature. Positive staining is represented as area of PAS staining per 10^6 pixels.

Congo Red Stain for Tissue Eosinophils

Paraffin sections were stained with Congo red as previously described [20]. Eosinophils were counted in a blinded manner in

four randomly selected high-powered fields for each section and 8 sections per group were analyzed. Eosinophil numbers are represented as number of eosinophils per high-power field.

Statistical Analysis

All data are represented as mean $\pm$ SEM. Statistical significance was determined by unpaired Student's *t* test using GraphPad Prism version 4.0.3 (GraphPad Software, San Diego, Calif., USA). Statistical significance was achieved when $p < 0.05$.

Results

Activation of Innate Immunity after Allergen Sensitization and Challenge

LPS tolerance was induced by direct intratracheal instillation of LPS for four consecutive days. Both allergen sensitization and challenge were also carried out by intratracheal exposure without the use of adjuvants. Because adjuvants are thought to artificially skew the immune system toward a Th2 response, their use is controversial [21]. By using a clinically relevant allergen and the natural route of exposure, the model used in the current study more accurately recapitulates the clinical setting.

Previous studies of LPS tolerance have defined it as a transient phenomenon. It is generally accepted that if more than 72–96 h elapses between initial LPS exposure and rechallenge, the acute inflammatory response is not attenuated [22–24]. Twenty-four hours after LPS tolerance induction, mice were sensitized with CRA and challenged with CRA on days 14 and 21. Figure 1 shows that LPS tolerance has no lasting effect on the mediators of innate immunity measured here. No difference in neutrophil numbers or concentrations of the CXC chemokines KC (CXCL1) and MIP-2 (CXCL2) in the BAL fluid was observed. More importantly, we saw no lasting defect in the ability of LPS-tolerant mice to produce TNF α (fig. 1d). Interestingly, LPS-tolerant mice produced more TNF α in response to allergen challenge.

Pulmonary Function Tests and Mediators of AHR

We next examined whether LPS tolerance can modulate AHR in response to allergen sensitization and challenge. Mice were exposed to increasing doses of aerosolized methacholine at 4 h after final allergen challenge. Our laboratory routinely observes robust AHR at this timepoint. LPS-tolerant mice had significantly attenuated AHR compared to nontolerant mice in response to 50 mg/ml methacholine (fig. 2a). Although the relevance of whole-body plethysmography has been demonstrated recently, the correlation of PenH to airway function is still

Fig. 1. Neutrophil numbers and mediators of innate immunity after final allergen challenge. Cytospin preparations from cells collected in the BAL fluid were made and 300 cell differential counts performed to determine the absolute numbers of neutrophils (a). Concentrations of chemokines CXCL1 (b), CXCL2 (c) and TNF α (d) in the BAL fluid were measured by standard ELISA. Data are presented as mean $\pm$ SEM (n = 4 mice per group per experiment; combination of 3 separate experiments).

Fig. 2. Measurement of airways hyperresponsiveness, airway resistance and cysteinyl leukotrienes after final allergen challenge. **a** For unrestrained, whole-body plethysmography, mice were challenged with increasing concentrations of aerosolized methacholine at 4 h after the final challenge and PenH values are represented as percent above baseline. **b** For invasive measurements, mice

were challenged with methacholine, as described in 'Materials and Methods', and pulmonary resistance is expressed as R cm H₂O/s/ml. **c** Cysteinyl leukotrienes were measured in the BAL fluid 2 h after final challenge. Data are presented as mean $\pm$ SEM. Experiments were done a minimum of 3 times with 3–4 mice per group, per experiment. * p < 0.05 compared to nontolerant group.

controversial [25]. Therefore, we also verified these findings using invasive pulmonary function tests. Invasive tests demonstrated a trend toward decreased lung function in LPS-tolerant mice after administration of 25 mg/ml methacholine, confirming the AHR data (fig. 2b). We were unable to administer higher doses of methacholine

directly to the trachea due to technical limitations of the assay. We then measured cysteinyl leukotrienes in the BAL fluid at 2 h after final challenge as a possible mechanism responsible for the decreased airway resistance. Interestingly, cysteinyl leukotriene production was significantly increased in LPS-tolerant mice, suggesting that

Fig. 3. PAS staining and quantification. Representative images of PAS stained nontolerant (a) and tolerant mice (b) 24 h after final allergen challenge. c The amount of positive PAS staining was quantified using NIH ImageJ software and expressed as area of

PAS staining per area of the entire lung section. Data are presented as mean $\pm$ SEM (n = 4 mice per group, per experiment; combination of 3 separate experiments). ** p < 0.01 compared to nontolerant group.

leukotrienes are not primarily responsible for AHR in this model (fig. 2c).

PAS staining was performed in lung sections harvested at 24 h after final challenge. We observed decreased mucus staining in the airway epithelial cells of LPS-tolerant mice compared to the nontolerant group (fig. 3a, b). Quantification of this staining using the NIH ImageJ software confirmed these observations, showing significantly less PAS staining in the tolerant lungs (fig. 3c).

Eosinophil Influx and Eosinophil-Specific Chemokine Production

Eosinophil infiltration is a cardinal feature of the late phase of the asthmatic response [26]. Absolute numbers of eosinophils in the BAL fluid of LPS-tolerant mice were significantly reduced (fig. 4a). This was accompanied by a concomitant decrease in eotaxin-1 (CCL11) and eotaxin-2 (CCL24) concentrations in the BAL fluid (fig. 4b, c). In order to rule out the possibility that reduced BAL chemokine expression was causing eosinophils to sequester in the lung parenchyma, we measured EPO activity as an indicator of eosinophil presence in the lung tissue. EPO activity 24 h after final challenge, as well as lung homogenate CCL11 and CCL24 concentrations were significantly decreased in LPS-tolerant mice (fig. 4d–f). No difference in RANTES (CCL5) production was measured (data not shown).

Eosinophil numbers in the parenchyma were further confirmed by Congo red staining of paraffin-embedded lung sections. Eosinophils were identified by cellular and nuclear morphology, as well as pink cytoplasmic amyloid staining. Representative digital images of nontolerant and tolerant lungs show an apparent reduction in eosino-

phil numbers in the tolerant lungs (fig. 5a, b). Quantification of these sections clearly demonstrates decreased numbers of eosinophils in the lungs of LPS-tolerant mice (fig. 5c).

Th1 and Th2 Cytokine Production in BAL Fluid

Asthma is largely characterized as a Th2-mediated disease characterized by high concentrations of IL-4 and IL-5, and low levels of IFN γ [27]. We investigated whether LPS tolerance alters the production of Th1 and Th2 cytokines, possibly skewing the inflammatory response to one mediated primarily by IFN γ . We found a slight increase in BAL concentrations of IFN γ , IL-4, IL-5 and IL-13 in LPS-tolerant mice at 2 and 24 h after final challenge, although this did not reach statistical significance (fig. 6). Also, no statistical difference was seen in BAL IL-12 (data not shown). While LPS tolerance protects against eosinophilia, and AHR, LPS-tolerant mice are still capable of robust cytokine production.

Antibody Production in Response to Allergen Sensitization and Challenge

Cross-linking of allergen-specific IgE on the surface of mast cells causes degranulation, and release of histamines, cytokines, and leukotrienes, which can cause subsequent AHR and epithelial damage [28, 29]. Plasma levels of total IgE were significantly decreased in LPS-tolerant mice, and were comparable to those measured in naïve animals (fig. 7a). A slight decrease in CRA-specific IgE was measured in LPS-tolerant mice receiving immunization only (fig. 7b). We further sought to determine whether LPS tolerance suppressed the production of IgG1, associated with Th2 responses, and IgG2a, associ-

Fig. 4. Eosinophil recruitment and production of eosinophil-specific chemokines in response to allergen challenge. Cytospin preparations from cells isolated from the BAL fluid were made and 300 cell differential counts performed to determine the absolute numbers of eosinophils at 24 h after final challenge (**a**). Concentrations of the chemokines CCL11 (**b**) and CCL24 (**c**) in the BAL fluid were measured by standard ELISA. **d** Eosinophil peroxidase activity was measured in the lung tissue after BAL at 24 h after final challenge. Concentrations of CCL11 (**e**) and CCL24 (**f**) in the lung homogenate (LH) were assayed by standard ELISA. Data are presented as the mean $\pm$ SEM (n = 4 mice per group, per experiment; combination of 3 separate experiments). * $p < 0.05$, *** $p < 0.0001$ compared to nontolerant group.

Fig. 5. Eosinophil staining and quantification of lung sections. Representative images of paraffin sections from nontolerant (**a**) and tolerant (**b**) mice at 24 h after final allergen challenge were stained with Congo red. Eosinophils were identified by morphol-

ogy and red cytoplasmic staining. **c** Number of eosinophils per high-power field was quantified. Data are presented as mean $\pm$ SEM (n = 4 mice per group, per experiment; combination of 3 separate experiments). *** $p < 0.001$ compared to nontolerant group.

Fig. 6. Th1 and Th2 cytokine production in BAL fluid at 24 h after final allergen challenge. Th1 cytokine IFN γ (a) and Th2 cytokines, IL-4 (b), IL-5 (c) and IL-13 (d) were assayed by ELISA. Data are presented as the mean $\pm$ SEM (n = 4 mice per group, per experiment; combination of 3 separate experiments).

ated with a Th1 phenotype [30]. Total IgG1 was significantly increased in immunized-only mice, but no difference in IgG1 or IgG2a was measured after immunization and challenge (fig. 7c, d). This indicates that LPS tolerance induces specific inhibition of IgE in this model.

Discussion

The effect of activators of the innate immune system on the development of the adaptive response to allergen has become an important focus of investigation. Epidemiological studies have produced conflicting results with regard to the effect of repeated LPS inhalation. Animal models have correlated high-dose LPS exposure with decreased allergen sensitization, whereas low levels of LPS seem to potentiate sensitization [31, 32]. Wang et al. [33] showed that intranasal exposure to LPS in neonatal mice protected from ovalbumin sensitization and resulted in increased regulatory T cell numbers. Further, it has been shown that TLR4 signaling is required for the development of antigenic tolerance in previously sensitized mice, but is not required for the development of sensitization [34]. In a recent rodent study, administration of a mono-

clonal TLR4 agonist prior to ovalbumin sensitization significantly attenuated airway eosinophilia, mucus production and AHR [35]. Our novel findings demonstrate that protection from allergen sensitization can be directly attributed to pulmonary tolerance to LPS. However, we employed a crude LPS preparation, and our allergen mixture contains many innate immune-activating compounds. Therefore, it is likely that this phenomenon is mediated by TLR4 as well as other pattern recognition receptors.

In this model, LPS tolerance was induced by four consecutive days of high-dose intratracheal LPS administration, followed by induction of asthma by intratracheal exposure to CRA. Few investigators use intratracheal delivery of environmentally relevant allergens for the study of asthma-like inflammation [36–38]. Most models utilize ovalbumin, which is not an environmental allergen, and employ an average of 6 exposures and a total of 2,000 μ g of allergen, while our model requires 3 exposures and a total of only 4 μ g of allergen [39–41]. This is potentially explained by the inherent protease activity present in cockroach frass and gastrointestinal proteins, which may facilitate antigen uptake by dendritic cells in the lung [42, 43]. The ability to induce asthma-like pulmonary inflam-

Fig. 7. Plasma antibody production in response to allergen sensitization and challenge. IgE (a), CRA-specific IgE (b), IgG1 (c) and IgG2a (d) were measured in plasma collected at day 22 after sensitization by standard ELISA. The Imm. Only group received CRA sensitization, but no challenge on days 14 or 21. Data are presented as the mean $\pm$ SEM ($n = 4$ mice per group, per experiment; combination of 3 separate experiments). * $p < 0.05$ compared to naïve mice as measured by Student's t test.

mation with relatively low concentrations of allergen may lie not only in the use of an environmentally relevant allergen, but also in the substantial LPS contamination naturally present in the allergen preparation. Therefore, our model recapitulates the environmental setting in which LPS contamination is ubiquitous. Our model also demonstrates the physiologically relevant adjuvant effects of LPS, as other compounds, such as Freund's adjuvant can cause artificial skewing toward a Th2 immune response [21].

The current findings demonstrate that the modulation of innate immunity induced by LPS tolerance is transient. CXC chemokine production and neutrophil recruitment are not affected 21 days after LPS tolerance was induced

(fig. 1). Further, decreases in $\text{TNF}\alpha$, a hallmark feature of the LPS-tolerant phenotype, are no longer present. Immune activation induced by LPS tolerance is protective against allergen sensitization, while one exposure to low-dose LPS, concomitant with sensitization (nontolerant group) potentiates the development of asthma.

Our data demonstrate a significant decrease in CRA-specific IgE in LPS-tolerant mice receiving only immunization, but no difference is measured in mice receiving both allergen challenges, while an opposite trend was measured in total IgG1. This can be partially explained in that the effects of LPS tolerance are no longer present at the time of the first allergen challenge (day 14). Therefore, antibody production in response to the first chal-

lenge is equivalent between groups. The differential regulation of these two isotypes (increased IgG1 and decreased IgE) may be mediated by the cytokine milieu present in the microenvironment of naïve B cells. Previous studies have reported that TGF β and IL-10 can inhibit IL-4-mediated class switch recombination to IgE, a role for TGF β in mediating endotoxin tolerance has been confirmed [44–46]. TGF β was also shown to have no effect on IL-4-mediated class switch to IgG1 [47]. Therefore, while mediators such as TGF β may inhibit IgE production, other cytokines such as IFN γ may drive IgG1 production [47]. Our data also demonstrated a significant reduction in total IgE in immunized-only LPS-tolerant mice, as well as those receiving both allergen challenges. This is likely due to the production of polyclonal IgE in response to LPS [48]. When LPS signaling is attenuated (LPS tolerance), total IgE production is inhibited.

We also determined that the mechanism underlying decreased eosinophilia is the reduction in CCL11 and CCL24 in both the BAL fluid and organ homogenate. We hypothesized that if the lack of eosinophils in the alveolar space and lung tissue was purely the result of a defective chemotactic gradient, increased numbers of circulating eosinophils would be present. Analysis of the peripheral blood showed no differences in circulating eosinophils in nontolerant mice compared to the LPS-tolerant group (data not shown). Further, IL-5 is a key mediator in eosinophil activation and egress from the bone marrow into sites of inflammation [49]. Plasma IL-5 levels were below the limit of detection (data not shown) of our ELISA (13.7 pg/ml); however, this does not rule out the possibility that concentrations below this limit are sufficient to mobilize eosinophils.

LPS-tolerant mice were protected from AHR, as well as airway resistance. We observed a dissociation between methacholine-induced airways hyperresponsiveness and cysteinyl leukotrienes. Our earlier studies also showed a similar protection from AHR and concomitant increases in cysteinyl leukotrienes [50]. We found that protection from methacholine-induced AHR was mediated

through a reduction in M2 and M3 muscarinic receptor expression [51]. It is of importance to determine whether muscarinic receptor downregulation lasts up to 21 days after LPS tolerance induction. The robust production of cysteinyl leukotrienes suggests that mast cell function is not impaired in the tolerant mice. Therefore, it is unlikely that the protection from AHR is mediated by the observed reduction in IgE. This dissociation between IgE and AHR has been demonstrated in mast cell and B cell-deficient mice [52, 53]. It is possible that the lack of mucus production seen in LPS-tolerant lungs contributes to the reduced airway resistance [54, 55]. Further, airway sensitization has been shown to induce a strong Th17 response leading to robust AHR [56]. We measured BAL levels of IL-17 and found no significant difference between groups at 2 or 24 h after final challenge (data not shown).

Taken together, our data show that prior inhalation of high doses of LPS protects against airway eosinophilia, AHR, mucus production and IgE. Further, these studies show that optimal allergen sensitization requires innate immune activation, and that this transient modulation of the innate immune response can have lasting effects on adaptive immunity. Further epidemiological studies are needed to determine whether lungs of individuals exposed to high levels of LPS are refractory to further LPS stimulation, which may confer protection against allergen sensitization.
