Fast-Track Surgery – Conditions and Challenges in Postsurgical Treatment: A Review of Elements of Translational Research in Enhanced Recovery after Surgery

Henry Hoffmann Christoph Kettelhack

Department of Surgery, University Hospital Basel, Basel, Switzerland

Key Words

Enhanced recovery after surgery • Fast-track surgery • Translational research

Abstract

Background: Enhanced recovery after surgery (ERAS) or fast-track surgery is a perioperative and postoperative care concept initiated in the early 1990s aiming to reduce the length of hospital stays following elective abdominal surgery. Twenty treatment items defined in the Consensus Guidelines established in 2009 were included in this concept. The success of ERAS depends highly on multidisciplinary teamwork and patient compliance. Several ERAS items and their impact on perioperative and postoperative care have recently been discussed. In this connection, translational research topics triggered increasing interest in ERAS and new impulses aimed at improving the ERAS concept. We thus reviewed the surgical literature to highlight the role of translational research items in ERAS. **Methods:** A literature search of Medline®, PubMed® and the Cochrane Database was performed. Two investigators independently reviewed the abstracts and appropriate articles were included in this review. **Results:** Articles have been selected. The advantages of the ERAS concept over conventional postoperative care were established by four meta-analyses and several reviews. But, due to the lack of standardization of the protocols, the

level of evidence is still low. The implementation of ERAS into clinical practice is furthermore hampered by the poor compliance with ERAS protocols and remains a challenge for the future. Moreover, recent trials challenge the role of some ERAS items, e.g. epidural anesthesia. Translational research trials investigating stress, immune and inflammatory response after surgery, new analgesic concepts, goal-directed fluid therapy and new drugs and substances to improve the outcome of ERAS provide first promising data but still need to be integrated in the ERAS concept. **Conclusion:** The Consensus Guidelines for ERAS are subject to the constant evolution of treatment strategies and implementation of translational research findings. Improvement of the compliance with ERAS protocols in surgical clinics and updating of ERAS items taking into account recent findings in translational research may improve the outcomes of ERAS but remain a long-term challenge in surgery for the next years.

Background

The concept of ‘fast-track surgery’ or ‘enhanced recovery after surgery’ (ERAS) initiated by Kehlet [1] in the 1990s has been described in numerous studies in the last decade. The main goal of this concept is a reduction in the postoperative length of hospital stay (LOS). This is

achieved by improved postoperative recovery using a multidisciplinary team approach maintaining cardiovascular, pulmonary, gastrointestinal, neurological and humoral functions. Following the first publications reporting a reduction in LOS to 2–3 days [2] and the implementation of Consensus Guidelines for ERAS [3], randomized studies revealed promising results favoring ERAS over conventional postoperative care [4]. The superiority of the ERAS concept has been further underlined by meta-analyses [5, 6]. Lately, investigators increasingly aimed to study the impact of individual ERAS items (table 1) on the overall postsurgical outcome. These items have been investigated and discussed and led to a continuous evolution and variation of the original ERAS concept. Furthermore, improvement of the collaboration among involved treatment groups (e.g. general practitioners, nurses, anesthesiologists, pain teams, social care workers, outpatient departments and rehabilitation institutions) is one of the major challenges in ERAS.

After studying the impact of individual items on the overall outcome of the ERAS concept and their translation into clinical practice, new items and inputs from translational research drew the attention of scientists. Among these, humoral, metabolic, inflammatory and immune response after surgery, change in analgesic modalities and medical treatments, the role of tissue oxygenation and microcirculation, and goal-directed fluid therapy (GDT) were the main topics in translational research.

We reviewed the surgical literature on the ERAS items with a particular focus on translational research, regarding their impact and possible implementation into the ERAS concept.

Methods

Search Criteria and Data Extraction

We performed a review of the literature on ERAS, fast-track surgery and translational research identified by using Medline® and PubMed® and the Cochrane databases to give an overview regarding clinical studies, basic research findings and future challenges. The following key words were: ‘enhanced recovery after surgery’, ‘ERAS’, ‘fast track surgery’, ‘postoperative ileus’, ‘length of hospital stay’, ‘laparoscopy’, ‘mast cells’, ‘gastrointestinal motility’, ‘immune response in surgery’, ‘inflammation response in surgery’, ‘tissue oxygenation’, ‘analgesic concept’ and ‘goal directed fluid management’.

With respect to the low evidence level in several translational research topics, original articles, clinical trials (phases I–III), comparative studies, results of consensus conferences, controlled clinical trials, in vitro studies, clinical studies, scientific reviews, meta-analyses and randomized controlled trials were eligible for this study. Regarding ERAS, only higher-evidence publications,

e.g. meta-analyses, randomized controlled trials (RCTs) and reviews have been included in this study. The authors preliminarily reviewed abstracts, and studies not meeting the inclusion criteria were excluded.

Results

The ERAS Concept

Although recent meta-analyses [5, 6] proved that ERAS has a better outcome compared with conventional postoperative care, there is still a lack of standardization in these studies [7], which hinders achievement of higher levels of evidence. Routine use of ERAS protocol is safe [8], but compliance with ERAS protocols is only slowly improving in surgical clinics [9]. The main problem is the multidisciplinary integration of ERAS into routine clinical care, challenging surgeons, anesthesiologists, nurses, general practitioners and other involved health care professionals [10, 11].

Following numerous clinical studies, Lassen et al. [3] summarized 20 treatment items as Consensus Guidelines, which need to be considered when ERAS is used in clinical practice. Fifteen out of 20 items reached evidence grade A in ERAS (table 1).

Implementation of ERAS into Clinical Practice

Although compliance with ERAS protocol is increasing there is still a lack of standardization of using ERAS modalities [6, 12]. Several publications mention different ERAS items that have been included into their protocols, highlighting the ongoing evolution of ERAS protocols.

Ahmed et al. [7] have performed an interesting systematic review of the compliance with ERAS items. They identified 19 ERAS modalities (table 2) partially differing from the Consensus Guidelines (20 items) and included 11 clinical trials. They showed that none of the trials included all 19 ERAS items in their protocols. In fact, they identified a maximum of 14 items included by Ramirez et al. [8], 13 modalities included by Nygren et al. [13] whereas Schwenk et al. [14] and Kahokehr et al. [15] considered only 4 items. Ahmed et al. [7] reported that both clinical implementation (items not reported or included in the ERAS protocol) and compliance (in percent) showed widespread variation among the clinics (table 2), highlighting the necessity of further standardization. This improved the evidence in ERAS protocols, as shown in a recent Cochrane meta-analysis including only 4 RCTs [6]. Although a high compliance with the ERAS protocol is clearly correlated with improved outcome after surgery

Table 1. ERAS items according to the Consensus Guidelines and health professional responsibility (adapted from Lassen et al. [3])

Item	Content	Responsible team member	Grade of evidence
1 Preadmission information and counseling	Patients should receive oral and written preadmission information describing what will happen during hospitalization, what they should expect, and what their role is in the recovery process	Surgeon	–
2 Preoperative bowel preparation	Patients undergoing elective colonic resection above the peritoneal reflection should not receive routine oral bowel preparation (grade A). Bowel preparation may be considered in patients scheduled for low rectal resection where a diverting stoma is planned	Nurses	A
3 Preoperative fasting and preoperative carbohydrate loading	The duration of preoperative fasting should be 2 h for liquids and 6 h for solids (grade A). Patients should receive carbohydrate loading preoperatively (grade A)	Nurses	A
4 Preanesthetic medication	Patients should not receive medications known to cause long-term sedation, from midnight prior to surgery. Short-acting medications given to facilitate insertion of epidural catheters are acceptable (grade A)	Anesthetist	A
5 Prophylaxis against thromboembolism	The preferred methods for prophylaxis in patients undergoing elective colorectal surgery are subcutaneous low-dose unfractionated heparin or subcutaneous low molecular-weight heparin (grade A)	Nurses	A
6 Antimicrobial prophylaxis	Patients undergoing colorectal resection should receive single-dose antibiotic prophylaxis against both anaerobes and aerobes about 1 h before surgery (grade A)	Anesthetist	A
7 Standard anesthetic protocol	Long-acting opioids should be avoided in patients undergoing anesthesia. Patients should receive a midthoracic epidural analgesia commenced preoperatively and containing local anesthetic in combination with a low-dose opioid (grade A)	Anesthetist	A
8 Preventing and treating postoperative nausea and vomiting	Prevention of postoperative nausea and vomiting should be induced if 2 risk factors are present. Treatment should be immediate, with combinations of the drugs discussed	Anesthetist	–
9 Laparoscopy-assisted surgery	Laparoscopic colonic resection is recommended if the surgeon or department is proficient with the technique and prospectively validated outcomes show at least equivalence to open surgery (grade A)	Surgeon	A
10 Surgical incisions	A midline or transverse laparotomy incision of minimal length should be used for patients undergoing elective colorectal resection	Surgeon	–
11 Nasogastric intubation	Nasogastric tubes should not be used routinely in the postoperative period (grade A). They should be inserted if ileus develops	Surgeon	A
12 Preventing intraoperative hypothermia	Intraoperative maintenance of normothermia with an upper-body forced-air heating cover should be used routinely (grade A)	Anesthetist	A
13 Perioperative fluid management	Intraoperative and postoperative fluid restriction in major colonic surgery with avoidance of hypovolemia is safe (grade A). When compared with excessive fluid regimens, normovolemic regimens in major colonic surgery lead to better outcomes (grade A). Intraoperative goal-directed therapy (e.g. with transoesophageal Doppler monitoring) is superior to a non-protocol-based standard with respect to outcome (grade A) and should be considered on an individual basis	Anesthetist	A
14 Drainage of peritoneal cavity following colonic anastomosis	Drains are not indicated following routine colonic resection above the peritoneal reflection (grade A). Short-term (24-hour) use of drains after low anterior resections may be advisable	Surgeon	A
15 Urinary drainage	Suprapubic urinary drainage for pelvic surgery is recommended (grade A). For colonic surgery, both suprapubic and urethral techniques are appropriate	Surgeon	A

Table 1 (continued)

Item	Content	Responsible team member	Grade of evidence
16 Prevention of postoperative ileus	Midthoracic epidural analgesia and avoidance of fluid overload are recommended to prevent postoperative ileus (grade A). A laparoscopic approach is recommended if locally validated (grade A). A low-dose postoperative laxative, such as magnesium oxide may also be considered.	Multi-disciplinary	A
17 Postoperative analgesia	Patients should receive continuous epidural midthoracic low-dose local anesthetic and opioid combinations (grade A) for approximately 48 h following elective colonic surgery and approximately 96 h following pelvic surgery. Acetaminophen (paracetamol) should be used as a baseline analgesic (4 g/day) throughout the postoperative course. For breakthrough pain, epidural boluses should be given while the epidural is running. Nonsteroidal anti-inflammatory drugs should be started at removal of the epidural	Multi-disciplinary	A
18 Postoperative nutritional care	Patients should be encouraged to commence an oral diet at will after surgery (grade A). Oral nutritional supplements should be prescribed (approximately 200 ml, energy dense, 2 or 3 times daily) from the day of surgery until normal food intake is achieved. Continuation of oral nutritional supplements at home for several weeks is recommended for nutritionally depleted patients (grade A)	Nurses	A
19 Early mobilization	Patients should be nursed in an environment that encourages independence and mobilization. A care plan that facilitates patients being out of bed for 2 h on the day of surgery and 6 h thereafter is recommended	Nurses	–
20 Audit	A systematic audit should be performed to allow direct comparison with other institutions	Multi-disciplinary	–

[7], pure facts do not seem to be convincing. A recent opinion survey of 1,390 surgeons in Germany and Austria revealed that implementation in routine surgical practice is not widely practiced [9]. Therefore, the challenge consists in a modification of traditional treatment strategies, overcoming interdisciplinary borders, accepting new ideas and coordination of the ERAS modalities in a prescheduled work flow by the responsible health professional (table 1).

Impact of the ERAS Protocol on Surgical Outcome Parameters

Postoperative Ileus in ERAS

The development of postoperative ileus (POI) as one of the major adverse events following abdominal surgery is based on the disturbance of the 'migration motor complex' [16]. POI has been characterized as an independent predicting factor for a prolonged LOS [17] and as the major factor accounting for in hospital morbidity regardless the type of operation [18]. Laparoscopy as part of the ERAS concept with limited surgical trauma has been

shown to reduce POI significantly [19]. As shown in RCTs, routine bowel preparation for abdominal surgery had no effect on POI [20]. Several inter- and intracellular mechanisms and their role in POI are the focus of translational research (see below).

LOS in ERAS

Several studies reported a significant reduction in LOS when ERAS was compared with conventional postoperative care [21, 22] without increased readmission rates [21, 23]. A direct relationship between compliance with the ERAS protocol and a reduction in LOS was shown in further studies [7]. Vlug et al. [24] identified predictors for reduced LOS in ERAS, such as early, enforced mobilization, female gender, laparoscopic surgery and normal oral diet. Complications like POI [17] and increased postoperative pain [25] are predictors for extended LOS. Furthermore, nonmedical reasons like outpatient resources or limited social care facilities challenge LOS [10]. The use of laparoscopy significantly reduced LOS [18] and is therefore an implemented part of ERAS. In contrast, the

use of epidural analgesia, one of the items in the Consensus Guidelines [3], has no effect on LOS and mobilization [26, 27] and hence should be critically investigated as to its impact on LOS and ERAS.

Postoperative Complications in ERAS

A correlation between ERAS and postoperative complications has been discussed. While randomized studies found decreased postoperative complications using ERAS [21, 23], other publications showed at least comparable complication rates in ERAS and conventional postoperative care [22], challenging a clear advantage for ERAS protocols. Regarding the surgical approach, some authors reported reduced complications using minimally invasive techniques in RCTs [28]; another case-control publication failed to support this tendency [29]. The long-standing doctrine of routine use of nasogastric tubes and delayed oral feeding in major abdominal surgery in order to prevent complications has been disproved by a recent Cochrane analysis [30].

Laparoscopy in ERAS

Although laparoscopy plays an important role in elective and emergency abdominal surgery, and is widely used as a standard procedure in abdominal surgery, the value of laparoscopy in the ERAS concept has been investigated in clinical studies. Whereas ERAS has been shown to be beneficial in open surgery [22], several RCTs support the superiority of laparoscopy in ERAS [4, 28]. A recent 4-arm-trial comparing laparoscopic with open surgery and ERAS with standard postoperative care showed that laparoscopy combined with fast-track care (ERAS) leads to faster recovery of gastrointestinal motility and improves clinical recovery [31]. Although the operation costs and the rate of reoperations in laparoscopy are higher compared with conventional open surgery in ERAS [21], laparoscopy reduces complications, POI, LOS and the rate of admissions to intensive care units [19, 21, 31] and, therefore, legitimately becomes a key item in ERAS.

Analgesic Concepts in ERAS

The postoperative pain concept in ERAS is part of an ongoing debate and still needs to be defined. Increased implication of the anesthetist and the development of dynamic analgesic regimens seem to be mandatory in further ERAS practice [32, 33].

A literature review regarding the impact of epidural anesthesia as one of the initial analgesic items in ERAS [3] provides different results regarding its effectiveness and role within the ERAS concept. A Cochrane analysis

Table 2. Implementation of (N/A) and adherence to ERAS items in clinical practice (adapted from a systematic review by Ahmed et al. [7] 2009)

ERAS item	N/A	Adherence to ERAS items of reporting studies, %
<i>Preoperatively</i>		
Counseling and education	5/11	87–100
No bowel preparation	4/11	0–100
Carbohydrate loading	4/11	61–100
No premedication	7/11	0–60
Curtailed fasting	10/11	61
<i>Intraoperatively</i>		
Active warming	7/11	79–100
High inspired O ₂ (80%)	10/11	95
Epidural analgesia	0/11	8–100
Transverse incision	8/11	25–96
No use of NG tubes	5/11	0–95
Restricted i.v. fluids	8/11	46–81
No use of drains	8/11	0–47
<i>Postoperatively</i>		
Early oral fluids	4/11	5–100
Early oral food	2/11	13–100
Early mobilization	1/11	5–100
Oral analgesia	7/11	70–100
Avoidance of opiates	9/11	67–78
Postoperative laxatives	10/11	100
Routine antiemetics	9/11	27–76

[34] and a further meta-analysis [26] comparing intravenous opioid analgesia with midthoracic epidural analgesia demonstrated the beneficial effect of epidural analgesia in preventing postoperative ileus. In contrast, its role in ERAS is diminished due to the fact that epidural anesthetics may cause hypotension and splanchnic hypoperfusion with an increased risk of cardiac events and anastomotic leaks [35]. Comparing epidural anesthetics with spinal anesthetics and patient controlled-anesthesia with opioids, spinal anesthetics and patient controlled-anesthesia were superior to epidural anesthetics regarding postoperative outcome [36]. Several studies demonstrated a positive effect of epidural anesthesia on outcome in open abdominal surgery [37, 38]. But its role in laparoscopic surgery is diminished by the fact that it was not correlated [36]. Additional studies demonstrated no reduction in LOS and earlier oral food intake by using epidural anesthetics [27].

Interestingly, there is a consensus on the fact that extensive intravenous opioid administration should be

avoided in ERAS; indeed, due to side effects and an increased rate of POI and LOS they should only be given to selected patients [39]. But this recommendation is challenged by the findings of Levy et al. [36, 40], who favor PCA using opioids or spinal anesthesia over epidural anesthesia in a systematic review and a clinical study. The role of COX-II inhibitors is well known: they mainly help reduce opioid consumption, and therefore should be part of multimodal pain management in ERAS [41].

Those results mitigate the role of epidural anesthesia in a laparoscopic surgery setting in ERAS, and protocols need to be reviewed and modified. Furthermore, the impact of PCA as a standard analgesic concept in ERAS needs to be reevaluated to clarify the controversial findings in the literature.

Translational Research in ERAS

After obtaining evidence using the ERAS concept in abdominal surgery [5, 6, 42, 43] and considering the controversial results when investigating the impact of separate ERAS items on outcome, several scientists lately concentrate on translational research. There are still unanswered questions, especially concerning the humoral, metabolic, inflammatory and immune response after surgery, the change in analgesic modalities, new pharmacological approaches, the role of tissue oxygenation and microcirculation, and the impact of GDT in perioperative care.

Inflammatory, Humoral and Immune Response after Surgery

Inflammation is the physiological reaction of vascularized tissue on manipulation, irritation and infection. This process is almost unavoidable in abdominal surgery with manipulation of the gut, where only a thin epithelial layer separates the microbial flora and the mucosal immune system.

Considering, that POI has been identified as one of the major factors for prolonged LOS and increased complications, the relationship between tissue inflammation and POI based on the concept of the 'motor migration complex' has recently been investigated. Neuronal innervation of the intestinal tract intensely communicates with the human immune system [44]. The complex interactions of mediators, e.g. interleukins (ILs) and tumor necrosis factor (TNF), induce invasion and degranulation of mast cells in the gut and subsequently lead to POI [45, 46]. Therefore, mast cell inhibition as a bona fide drug target could be one of the future treatment concepts to prevent POI [45]. In an experimental study, electric stim-

ulation of the vagus nerve and central activation of anti-inflammatory cholinergic pathways by intravenous semapimod (an inhibitor of p38 mitogen-activated protein kinase) reduced tissue inflammation and the appearance of POI [47].

A recent RCT including 597 patients [22] investigated the impact of ERAS on surgical stress response and thus the degree of inflammatory activation. Measuring the nutrition index, the metabolism index (hemoglobin, albumin, prealbumin, triglycerides, transferrin, and nitrogen balance) and the stress index (cortisol, TNF- α , IL-1 β , IL-6, and IFN- γ), the cascade of IL-1 β inducing polymorphonuclear cells to migrate to the microvascular system and stimulate macrophages to produce IL-6 and TNF- α was highlighted. Authors found a significant reduction in cortisol levels, IFN- γ and TNF- α levels in the ERAS group after surgery compared with the control group whereas IL-1 β remains little changed and IL-6 levels were higher in both groups. This immune cascade can be attenuated by ERAS compared with conventional postoperative care [22].

Considering the reduced manipulation using minimally invasive surgical techniques, the surgical approach and its impact on immune response came increasingly into the focus of investigation. Postoperative leukocyte (LC) function is restored earlier using laparoscopic surgery [48] and laparoscopy reduces the activation of mast cells and thus postsurgical inflammation and POI [49]. A recent meta-analysis including 13 studies demonstrated that open colorectal surgery for neoplasia is associated with higher serum levels of IL-6 and IL-1, inducing an intense immune and inflammatory response compared with laparoscopy [50]. In contrast, in another meta-analysis including 11 trials, sufficient evidence to support superior preservation of global immune function (T-suppressor lymphocytes CD8+, C-reactive protein) with laparoscopy could not be reached [51]. Therefore, the potential of postsurgical inflammatory reduction by laparoscopy needs to be investigated in further studies.

Anti-inflammatory effects of dexamethasone in ERAS have been discussed in several studies. A meta-analysis including 11 RCTs showed that preoperative single-dose glucocorticoid administration decreases the rate of postsurgical complications and LOS, most likely as a consequence of attenuating the inflammatory response after major abdominal surgery [52]. Another meta-analysis emphasized the role of dexamethasone in the multimodal analgesic concept, showing that at doses of more than 0.1 mg/kg it is an effective adjunct to reduce postoperative pain and opioid consumption [53].

The approach of perioperative immune nutrition has been investigated in a meta-analysis including 13 RCTs. Immune nutrition (e.g. glutamine, arginine, omega-3 polyunsaturated fatty acids and ribonucleic acids) had no significant effect on postoperative mortality, but had positive effects on postoperative infection rate, LOS and improved immune function, increasing total lymphocyte counts, CD4 levels, IgG levels and decreasing IL-6 levels [54]. The role of neuropeptides in gastrointestinal physiology and immune regulation followed by surgery still needs to be clarified [55].

Therefore, reduction in surgical stress and immune response with attenuated tissue inflammation by using minimally invasive surgery, neuropeptides, mast cell inhibitors, cytokine antagonists and glucocorticoids should be investigated in further studies.

New Approaches to Prevent POI

POI is thought to be a consequence several tissue level pathways. Subsequently, four major pathways induced complex immune cascades in the intestine leading to POI have been identified: the neurogenic, inflammatory, hormonal and pharmacological pathways [16]. At the site of surgical manipulation, intestinal macrophages produce mediators that lead to paralysis of the mucosal myocytes. The mechanism of activation of macrophages in physically untouched intestinal areas remains unclear. The immune response following manipulation during surgery involves dendrite cells, releasing a cascade of interleukins (IL-12), interferon- γ (INF- γ) and T-helper type 1 cells, which activate macrophages. Recently, Engel et al. [56] described POI as a T-helper type 1 cell-mediated disease and identified T-helper type 1 cells as potential targets for disease monitoring and therapy. Therefore, prevention of T cell migration, inhibition of IL-12, TGF- β and INF- γ are potential treatment targets which have to be further investigated.

In experimental studies, neuronal stimulation with prokinetic 5-hydroxytryptamine-4-receptor (5-HT₄R) agonists and dopamine receptor antagonists have been found to be potential therapeutic agents for directly ameliorating the motility disorder associated with POI [57]. Additionally, an experimental study showed that intestinal ghrelin (growth hormone release inducing) receptor agonists (TZP-101) improve large-bowel function in rats with POI following surgical manipulation, which suggests that it accelerates the upper gastrointestinal transit and shortens POI [58].

Our understanding of tissue level processes in POI has improved based on promising results from experimental

studies. More higher-evidence studies are necessary to further investigate new immune modulation drugs, their interaction in the complex immune cascade and their possible implementation in clinical practice.

Impact of Reduced Tissue Oxygenation

Adequate tissue oxygenation is one of the preconditions of healing and recovery although it is no original ERAS item. The level of tissue oxygenation is closely correlated with GDT using colloids. This is generally explained by the fact that colloid fluid administration expands the intravascular volume, improves microcirculation and therefore improves tissue oxygenation compared with crystalloids [59]. Supplemental oxygen administration in the peri- and postoperative phase leads to improved outcome and decreased morbidity [60]. A recent study shows a relation between tissue oxygenation and surgical approach. Laparoscopy was associated with higher levels of tissue oxygenation compared with open surgery although pneumoperitoneum with increased intra-abdominal pressure and the commonly used Trendelenburg position can disturb alveolar ventilation and compromise oxygenation during laparoscopic surgery [61]. The analgesic modality (e.g. epidural analgesia, spinal analgesia, patient-controlled analgesia) has no impact on oxygen delivery during laparoscopic surgery [62].

Summing up, adequate tissue oxygenation can be improved by adequate colloid fluid administration and laparoscopic surgery, and should become a constant item in the ERAS concept.

New Metabolic and Hormonal Aspects to Improve Postoperative Recovery

The surgical stress response can activate the hypothalamus-pituitary-adrenal axis, which leads to the release of glucocorticoids, causing postoperative insulin resistance [22]. Although insulin resistance is decreased by ERAS, additional perioperative intravenous glucose administration or preoperative carbohydrate drinks may be beneficial [63]. In an experimental study, corticotropin-releasing factor (CRF) was demonstrated to affect humoral stress response after surgery. CRF plays an important role in mediating the early phase of gastric ileus through activation of CRF-1 receptors, and therefore may be a potential target for medications preventing POI [64].

GDT and Colloids in ERAS

Perioperative fluid management has received increased interest in translational research. Only a few experimental studies provided first data that improved our

understanding the cellular processes in fluid administration. The advantages of fluid restriction with avoidance of hypovolemia as outlined in the Consensus Guidelines [3] were challenged in an experimental pig model study [64] comparing restricted crystalloids versus GDT with crystalloids versus GDT with colloids, which found lower tissue oxygenation and decreased microcirculation using fluid restriction. While colloid fluid administration with GDT improved the microcirculation also in unaffected and perianastomotic colonic tissue, interestingly the type of fluid administration (crystalloid, colloid, restricted) had no effect on the hemodynamic parameters.

As already mentioned in the Consensus Guidelines, GDT (e.g. with transesophageal ultrasound monitoring or a central venous catheter) is superior to a non-protocol-based standard with respect to outcome (grade A) and should be considered on an individual basis [3]. This individual approach includes optimization of flow-related parameters within the limits of the individual cardiac capacity. Several RCTs provided evidence that GDT also improves the outcome regarding nausea, vomiting, postoperative ileus and LOS [65]. But GDT alone does not improve the microcirculation and tissue oxygenation. It must be combined with colloid fluid administration to provide its positive effect on anastomotic healing [62]. Noblett et al. [66] highlighted the effect of GDT on the postoperative immune response, showing lower IL-6 levels in GDT and thus attenuation of stress-induced organ dysfunction.

In summary, colloids for GDT were used in several clinical and experimental studies, supporting the trend of better outcomes compared with crystalloids and providing longer intravascular microcirculation and tissue oxygenation.

New Pharmacological Aspects to Improve Postoperative Recovery (ERAS)

Several trials failed to establish a significant reduction in POI and LOS using well-known prokinetic medications (e.g. metoclopramide, cisapride, erythromycin or prostigmine) [67]. Therefore, a critical review of conventional medical approaches, the alternative use of local anesthetics and implementation of new medications (alvimopan, capsaicin and mosapride citrate) became the objective of translational research in ERAS.

Local anesthetics (e.g. lidocaine) are well known in surgery and widely used to prevent postoperative pain. Meta-analyses favored intraperitoneal administration of local anesthetics [68] and intravenous lidocaine administration, with clear advantages in patients undergoing major

abdominal surgery with faster return of bowel function and decreased LOS [69].

Capsaicin is a new substance, known to cause enhanced sensitivity to noxious stimuli, followed by a period with reduced sensitivity and persistent desensitization after repeated local applications. A meta-analysis based on the Cochrane database and including 6 RCTs showed that repeated application of a low-dose capsaicin cream (0.075%) or a single application of a high-dose (8%) patch may provide a degree of pain relief to some patients with painful neuropathic conditions [70]. Thus, its role in the multimodal pain concept improving ERAS needs to be further investigated.

Alvimopan, a selective intestinal μ -receptor opioid antagonist, has been the subject of several meta-analyses to investigate its impact on postoperative recovery, attenuation of negative effects of opioids and reduction in the occurrence of POI. The United States Federal Drug Administration (US FDA) approved alvimopan (Entereg®) in 2008 for oral intake before and after large and small bowel resection to prevent POI [71]. Although alvimopan has been shown to save overall hospital costs [72] and accelerate gastrointestinal recovery following major abdominal surgery [73], collection of further data appears to be important to reach higher levels of evidence and implementation in routine ERAS practice. This is all the more important, considering that recent data challenge its impact in laparoscopy [74] and its incorporation into ERAS practice is less than expected by the data [75].

New prokinetic medications are part of the ongoing discussion. Laxatives, e.g. magnesium oxide, did not show any beneficial effects in ERAS in a recent randomized study [76]. Mosapride citrate, a 5-HT₄R, reduced the occurrence of POI in a clinical study [77].

Conclusion

ERAS and its items have been the subject of several clinical trials that obtained significant evidence for improved postoperative outcome compared with conventional postoperative care. Based on the Consensus Guidelines [3], ERAS is subject to evolution regarding the clinical implementation and modification of its items. Although ERAS significantly decreases LOS and the overall occurrence of complications, compliance with its protocol in daily clinical practice worldwide is not optimal [7]. Considering multidisciplinary in ERAS, cooperation with anesthetists, nurses, physiotherapists, out-

patient care and general practitioners is mandatory to further improve implementation and thus the outcome and success of ERAS. This review further emphasizes that knowledge regarding underlying tissue level processes and complex immune inflammatory cascades is limited. First promising results from experimental and pharmacological studies need to translate into the clinical experimental setting with the aim of reaching higher levels of evidence.

Keeping up with the evolution of the ERAS protocol in the last decade, it may be challenging to omit individual items or replace and modify them in order to reach better outcomes. Several studies suggest that recovery after surgery may rather be influenced by the surgical approach than by the ERAS items per se, which may overreach minimally invasive techniques compared with the other ERAS items. There is no doubt that the role of epidural anesthesia especially in laparoscopy and ERAS needs to be reviewed critically due to controversial results, lack of evident data and side effects.

The humoral, immune and inflammatory response after abdominal surgery is one of the major topics in translational research. Since inflammatory processes are known to induce POI based on a cascade of mediators (IL, TNF), several tissue level treatment options have been investigated. Reduced activation of mast cells by laparoscopy, pharmacological stabilization of mast cell degranulation and central activation of cholinergic anti-inflammatory pathways are promising approaches to prevent POI. The surgical access seems to have an important impact, but its clinical significance regarding immune, inflammatory and humoral response and recovery is still uncertain and needs further research. Dexamethasone can reduce complications, LOS and inflammatory response in the clinical setting. But similarly to immune modulation and immune nutrition, its role in the ERAS concept needs further clarification. New approaches to prevent POI are based on intra- and intercellular processes. Since animal studies have revealed that POI is a T-helper type-1 cell-mediated disease, prevention of T cell migration, inhibition of IL-12, TGF- β and INF- γ is a potential treatment option, which has to be further investigated in clinical settings. Agonists of 5-HT₄R, of the dopamine receptor and the ghrelin receptor may be helpful to overcome POI and present interesting targets for further investigations.

Using laparoscopy rather than open surgery increases tissue oxygenation whereas the analgesic regimen has no effect on perioperative oxygen delivery. To reduce the postoperative insulin resistance, perioperative glucose

administration and preoperative carbohydrate drinks can improve the outcome and reduce LOS.

GDT facilitates faster recovery of gastrointestinal function (POI) and better microcirculation. But GDT needs to be combined with colloid fluid administration to provide its full effect. But still, there is a lack of data integrating GDT and colloid fluid administration in routine ERAS and the practicing anesthetist is still left with some unanswered questions.

New drugs have been investigated to improve the outcome in ERAS. Alvimopan is one of the new medications and has been increasingly used in clinical studies. It can reduce LOS and the occurrence of POI, but its clinical implementation into the ERAS concept is less than expected. Since the US FDA approved alvimopan (Entereg) in 2008, further clinical studies investigating the impact of alvimopan in the ERAS concept are needed. Capsaicin is only beneficial in local administration in chronic pain, which challenges its role in ERAS. Local anesthetics provide evidence-improving data in ERAS, considering its known use in local and regional anesthesia (e.g. TAP block), but also showed promising effects in reducing POI and LOS when administered intravenously.

In summary, the modalities of the ERAS protocol are subject to a constant evolution. It may be difficult significantly to improve the good results of the ERAS protocol by adding further items. Translational research topics may have higher potential for improving outcomes in ERAS. But considering the limited knowledge in basic research topics, further investigation of tissue level processes is mandatory.
