Abstract

Objective: Estrogen treatment limits the cytotoxic effects of chemotherapy in estrogen receptor-positive (ER+) breast cancer cell lines, suggesting that estrogen pathway signaling may confer chemotherapeutic resistance. This study investigates the molecular responses of ER+ breast cancer cell lines to the chemotherapeutic agent, doxorubicin, in the presence or absence of estrogen. Methods: ER+ MCF-7 and T47-D cells were cultured in hormone-starved or estrogen-containing media with or without doxorubicin at concentrations mimicking the low concentrations seen in plasma and tumor microenvironments in humans following typical bolus administration. Protein levels, phosphorylations, and interactions of estrogen-signaling molecules were assessed following these treatments, as well the effects of ER signaling inhibitors on cell proliferation. Results: Surprisingly, estrogen and doxorubicin co-treatment markedly induced pro-growth alterations compared to doxorubicin alone and modestly enhanced estrogen alone-induced changes. Several inhibitors suppressed cell proliferation in the presence of doxorubicin and estrogen. Conclusions: These findings demonstrate that molecular changes caused by doxorubicin in ER+ breast cancer cells can be reversed by estrogen, providing molecular evidence for the poorer responses of ER+ tumors to doxorubicin in the presence of physiologic estrogen levels. Our results also suggest that the addition of drugs targeting the ER, EGFR, the SFKs, MEK, PI3K, and/or the MMP proteins to a conventional chemotherapy regimen may improve chemo sensitivity.

Introduction

Breast cancer is the most commonly diagnosed and the second most deadly cancer in women [1]. Clinically, breast tumors can be classified by hormone receptor status, with estrogen receptor-positive (ER+) cancers occurring three times more often than estrogen receptor-negative (ER−) cancers [2]. Patients with ER+ tumors are often treated with hormonal therapies to reduce estrogen responses within the tumor and/or with chemotherapy. However, several clinical studies have reported that pa-
tients with ER+ tumors respond less well to chemotherapy than their counterparts with ER− tumors [3–5]. Laboratory studies using ER+ breast cancer cell lines have also demonstrated that the presence of physiologic estrogen levels counter the effects of chemotherapy, which may explain the clinical observation of mitigated doxorubicin sensitivity in ER+ tumors [6, 7].

Doxorubicin hydrochloride (Adriamycin, Rubex) is one of several commonly used chemotherapeutic agents in the treatment of ER+ breast cancer. It is typically administered to cancer patients as a bolus of 40–70 mg/m². Within about 2 hours of administration, the serum concentration rapidly decreases to levels of 10–100 nM, which are maintained for days [8–12]. Similarly, a study of 12 breast cancer patients given a 90 mg/m² bolus of epirubicin, an analog of doxorubicin, demonstrated that the average intratumoral concentration paralleled the mean plasma epirubicin level of 52 nM at 25 h following administration [13]. Investigations of breast cancer cell lines have shown that ≥1 μM concentrations of doxorubicin decrease cell viability, induce apoptosis, and cause cell cycle arrest [14–16]. However, little is known about whether and how the drug (especially at concentrations of 10–100 nM) affects cell proliferation, cell cycle progression, estrogen/estrogen receptor signaling, and whether estrogen effectors may mediate resistance to doxorubicin. Likewise, few studies explain how estrogen-mediated resistance may occur in estrogen-suppressed patients (i.e. post-menopausal patients, aromatase inhibitor (AI)-treated patients, oophorectomy patients, etc.). The concept of estrogen-mediated resistance is supported by findings of persistent mediators of estrogen signaling in both endocrine- and chemotherapy-treated patients [17–19].

Estrogen regulates the cellular proliferation, survival, and differentiation of many tissues [20–24] and acts by binding to its canonical receptors, ER-α and/or ER-β, in the cytoplasm or nucleus of treated cells. These receptors form homo- and heterodimers that, in turn, activate classical and rapid signaling cascades [25, 26]. Transcription resulting from classical signaling is measurable within hours of estrogen stimulation and results from either direct binding of dimerized ER proteins to estrogen response elements (EREs) upstream of estrogen-responsive genes or participation in non-ERE-dependent transcriptional complexes in the nucleus. Rapid estrogen actions occur in the cytoplasm within minutes of estrogen exposure and are characterized by increased phosphorylation and activation of many signaling molecules including ER-α, epidermal growth factor receptor (EGFR) family members, extracellular regulated kinase (ERK) 1/2, c-Src, and phosphoinositide 3-kinase (PI3K) [27, 28]. Short stimulations with estrogen also induce the formation of complexes between ER-α, c-Src, PI3K, and/or MNAR (modulator of non-genomic actions of the estrogen receptor, a scaffolding protein also known as PELP-1) as well as between the androgen receptor (AR) and ER-α or c-Src. Some of these complexes result in post-translational modifications that enhance downstream signaling and ultimately gene transcription [29–31]. Phosphorylation of ERK 1/2, c-Src, and PI3K can result in the activation of signaling cascades that regulate proliferation, survival, adhesion, and migration independently of and together with ER [28, 32]. Because of their involvement in estrogen action, these molecules are prime candidates for mediating resistance of ER+ breast cancer cells to chemotherapy.

Little is understood about the molecular effects of doxorubicin in the presence of estrogen on ER+ breast cancer despite extensive work with each chemical alone. This report tests the hypothesis that the doxorubicin resistance is mediated in part by estrogen pathway signaling. We seek to test the effects of doxorubicin and estrogen on various downstream components of estrogen-signaling pathway. Our model is designed to mimic the prolonged estrogen and doxorubicin exposures observed clinically. We show that prolonged estrogen treatment alone modulates total and phosphorylated levels of specific signaling molecules similar to short estrogen treatments. Doxorubicin (25 nM) alone modestly increases levels of several hormone and growth factor signaling molecules that are downregulated by estrogen alone, suggesting mechanisms by which doxorubicin counteracts the pro-survival effects of estrogen. Surprisingly, treatment with both estrogen and doxorubicin modestly enhances estrogen-induced changes and markedly induced pro-growth alterations compared to doxorubicin alone, providing molecular evidence for the poorer responses of ER+ tumors to doxorubicin in the presence of physiologic estrogen levels. We also test inhibitors of several proteins involved in estrogen signaling to identify molecules whose inhibition might decrease intrinsic doxorubicin resistance. We show that inhibitors of the ERK pathway and of MMPs (matrix metalloproteinases that activate growth factor receptor pathways) cooperate with doxorubicin to reduce cell proliferation, while inhibitors of ER(s), Src-family kinase (SKF) protein(s), AR, and PI3K function independently of doxorubicin. Both classes of inhibitors are potential candidates for overcoming doxorubicin resistance in ER+ breast cancers.
Materials and Methods

Reagents

17-β estradiol was purchased from Sigma-Aldrich Corporation (Saint Louis, Mo., USA) and resuspended in ethanol for storage. The final media concentration used in experiments (10 nM) contained no more than 0.001% ethanol. Doxorubicin hydrochloride was obtained from Calbiochem (San Diego, Calif., USA). For inhibitor experiments, PD-98059 (final concentration, 50 μM) was obtained from Biomol International (Enzo Life Sciences, Plymouth Meeting, Pa., USA), fulvestrant (1 μM) from AstraZeneca (Wilmington, Del., USA), GM 6001 (10 μM) from Biomol International, gefitinib (10 μM) from LC Laboratories (Woburn, Mass., USA), SU6656 (1 μM) from Calbiochem, and LY 295002 (25 μM) from Cayman Chemical (Ann Arbor, Mich., USA). All inhibitors were suspended in dimethyl sulfoxide (DMSO; Fisher Scientific) except fulvestrant, which was mixed with ethanol. The final concentration of inhibitors contained no more than 1% DMSO or ethanol. Unless otherwise specified, all other chemical reagents were purchased from Fisher Scientific (Waltham, Mass., USA).

Cell Lines

The human ER+ breast cancer cell lines T47-D and MCF-7 were acquired from ATCC (Manassas, Va., USA) and the A. Boutron lab (University of Virginia) and maintained at 37°C in a humidified 5% CO₂ environment. T47-D and MCF-7 cells were cultured in Dulbecco’s Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS, USA origin), 1 mM sodium pyruvate, and 1% penicillin/streptomycin. For hormone starvation, cells were cultured in phenol red-free, low glucose DMEM supplemented with 5% charcoal-stripped FBS, 2 mM L-glutamine, 1 mM sodium pyruvate, and 0.76% D-(+)-glucose (45% of full strength), designated ‘CSSM’. Except where noted, all liquid cell culture reagents were from Gibco (Billings, Mont., USA).

Growth Assay

For each condition tested, 5 × 10⁴ MCF-7 or 10⁵ T47-D cells were seeded per well in a 6-well dish (Corning, Corning, N.Y., USA) and incubated overnight. The next day, wells were washed three times with Dulbecco’s phosphate-buffered saline (DPBS, Gibco) and replenished with fresh starvation medium. Inhibitors were added to the appropriate wells after 23 h, and 10 nM estrogen was added 1 h later. In the absence of inhibitor, groups were incubated 24 h prior to estrogen addition. Cells were incubated an additional 24 h, and then the media was changed to fresh starvation medium with or without doxorubicin. Estrogen and inhibitors were added again to the appropriate groups, and cells were incubated another 48 h, trypsinized, and counted on a hemocytometer.

Cell Cycle Analysis

MCF-7 treatment groups of CSSM alone, CSSM plus estrogen (E), CSSM plus doxorubicin (Dox), and CSSM plus estrogen plus doxorubicin (Dox + E) were seeded in CSSM in triplicate at a density of 2 × 10⁶ cells per 10 cm dish (Greiner bio-one, Frickenhausen, Germany), incubated overnight, and cultured as described for the growth assay. Following a PBS wash (1.4 M NaCl, 26.8 mM KCl, 40.6 mM Na₂HPO₄ · 7H₂O), cells were detached with 5 ml/dis Accutase (Innovative Cell Technologies, San Diego, Calif., USA) and triplicate plates combined. All subsequent steps were at 4°C and utilized polypropylene tubes (Becton Dickenson, Franklin Lakes, N.J., USA). Cell clumps were broken apart by pipetting repeatedly, centrifuged for 6 min at 200 × g, and resuspended in 0.5 ml PBS. Cells were then fixed in 4.5 ml cold 70% ethanol (Fisher Scientific) in ddH₂O and stored at −20°C until analyzed. Just prior to analysis, ethanol-suspended cells were centrifuged 5 min at 200 × g, suspended in 1 ml cold PBS and counted by hemocytometer. One million cells were washed in cold PBS, pelleted, re-suspended in 1 ml DAPI/Triton X-100 staining solution (0.1% w/v Triton-X-100 (LabChem Inc., Pittsburgh, Pa., USA) and 1 μg/ml DAPI (Sigma-Aldrich) in ddH₂O) for at least 30 min in the dark. DAPI fluorescence was detected by a CyAn™ ADP LX 9 Color flow cytometer (Beckman Coulter, Brea, Calif., USA). The pulse width-pulse area signal was used to discriminate between G₁ cells and cell doublets and gate out the latter. Data were analyzed with the ModFit LT program, version 3.2.1 (Verity Software House, Topsham, Me., USA).

Western Blot Analysis

For each of the four treatment groups, cells were scraped, pelleted, and lysed in NP-40 lysis buffer (1% (v/v) NP-40, 20 mM Tris HCl, pH 8.0, 137 mM NaCl, 10% (v/v) glycerol, 2 mM ethylenediaminetetraacetic acid (EDTA)) supplemented with Protease Inhibitor Cocktail Set I (Calbiochem) and 100 μM Na₃VO₄, and clarified by centrifugation (9,300 × g, 5 min). The protein concentration of the lysates was quantitated with BioRad Protein Assay reagent (Hercules, Calif., USA) and the Multiskan MCC plate reader (Fisher Scientific).

Whole cell lysates were analyzed by Western blot (100 μg/lane). Proteins were separated on 8% SDS-PAGE gels and transferred to polyvinylidene fluoride membranes (Immobilon-P, Millipore, Temecula, Calif., USA). Membranes were blocked in 5% milk or BSA (w/v) in Tris-buffered saline TWEEN-20 buffer (TBST; 100 μM Tris base, 1.5 mM NaCl, 1% (v/v) TWEEN-20) for 1–2 h at room temperature and then incubated in a primary antibody solution (identical to blocking buffer) overnight at 4°C (see table 1 for details). Membranes were then thoroughly washed in TBST and incubated at room temperature with horseradish peroxidase-conjugated secondary antibody (goat anti-mouse or sheep anti-rabbit (GE Healthcare, Waukesha, Wisc., USA); both 1:2,000) for 1 h. Membranes were again thoroughly washed and incubated with SuperSignal West Pico Chemiluminescent Substrate (Thermoscientific, Waltham, Mass., USA) for 2 min in the dark. Membranes were exposed to film (Blue Lite Autorad film, ISC Bioexpress, Kaysville, Utah, USA) and processed.

Quantitation and Statistical Analysis

AlphaEaseFC version 3.1.2 (Alpha Innotech Corp., San Leandro, Calif., USA) was used to quantitate scanned protein bands on film. All total protein levels were normalized to the loading control. Specific phosphorylations were calculated by first normalizing the phospho- and total protein bands to the loading control and then dividing the normalized phosphorylated band by the normalized total protein. All conditions were divided by the value for the untreated control and expressed as the fold change of the control. Comparisons between treatment groups were carried out using Student’s t test or analysis of variance between groups (ANOVA) corresponding to factorial experiments done in randomized blocks after transforming values to the log scale (to account for experiment-to-experiment variation in growth). All error bars indicate standard errors of the mean (SEM).
Results

Doxorubicin Impairs Estrogen-Induced Proliferation

It has previously been shown that at the level of the tumor microenvironment, estrogen is present at levels likely sufficient for signaling even in post-menopausal or ovarian-suppressed patients [33]. In current standard of care, most patients receiving chemotherapy do not receive concurrent anti-estrogen therapy (AIs or SERMs), thus the hypothesis that estrogen signaling may counteract the effects of chemotherapy is clinically relevant.

In order to develop a cell culture system that would reflect the clinical treatment paradigm for ER+ breast cancers and allow us to address the biological and molecular questions regarding ER signaling, two ER+ breast cancer cell lines (MCF-7 and T47-D), which are dependent on estrogen for growth and survival, were treated as depicted in figure 1. Cells were hormone-starved and exposed to 10 nM estrogen alone, doxorubicin alone, estrogen and doxorubicin together, or maintained in hormone depleted conditions for a 5-day period. Following treatment, cells were assessed for protein levels and phosphorylation status of molecules involved in estrogen signaling by immunoprecipitation/Western blot or for biological responses, such as proliferation, cell death, and cell cycle progression. Figures 2–6 depict representative results of these studies and are described in more detail below.

Previous studies have shown that ER+ breast cancer cells treated with <1 μM doxorubicin can survive in the presence of estrogen [6, 7], suggesting that in the presence of the sub-lethal doxorubicin concentrations achievable in human tumors, ER+ breast cancers must be able to employ resistance mechanisms (e.g. estrogen-mediated, SFK-mediated, cell cycle arrest, IGFR-mediated, etc.). Given this, we sought to establish the biological effect of nanomolar concentrations of doxorubicin in our system. MCF-7 and T47-D cells were exposed to doxorubicin in the presence or absence of estrogen (according to the scheme in fig. 1) and counted after 5 days as a measure of the cumulative net growth and survival of cells in an estrogenic environment prior to and during doxorubicin treatment. Figure 2a shows that estrogen-induced proliferation was diminished in both cell lines with increasing

† Waller et al. [82]. * Reuter et al. [86].
Doxorubicin and Estrogen in ER+ Breast Tumors

Doxorubicin concentrations, with an approximate 50% decrease at 25 nM in MCF-7 cells. Since the estrogen response in MCF-7 cells in the absence of doxorubicin was more robust than in T47-D cells, and the 25-nM drug concentration permitted an analysis of both estrogen and doxorubicin effects, this doxorubicin concentration and MCF-7 cells were chosen for all subsequent experiments. Within the doxorubicin range tested (0–1 μM) and in the absence of estrogen, little change in cell number was observed, consistent with the finding that doxorubicin is most cytotoxic for proliferating cells, and ER+ cells require estrogen for proliferation [34, 35]. Apoptosis was also not detected above background by the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) or poly(ADP-ribose) polymerase (PARP) cleavage assays, nor was a change in cell death observed by the trypan blue assay in either cell line (data not shown). In contrast, ER-BT-20 breast cancer cells were not dependent upon estrogen for proliferation and demonstrated significant reductions in cell number upon doxorubicin treatment, even in the absence of estrogen (online suppl. data I; for all online supplementary material, see www.karger.com/doi/10.1159/000341394). These results raised the question of what effect, if any, doxorubicin might have on cell cycle progression in ER+ breast cancer cells, in both the absence and presence of estrogen. To address this question, MCF-7 cells were either left untreated or treated with 25 nM doxorubicin alone or together with estrogen for 5 days and subjected to cell cycle analysis by flow cytometry as a point-in-time measure of the effect of doxorubicin. Figure 2b shows that doxorubicin alone-treated cells arrested in G1, and fewer progressed to S phase compared to non-treated cells, consistent with prior reports and further affirming the validity of our model system [16, 36]. Cells treated with doxorubicin and estrogen together exhibited a similar G1 accumulation and decrease in S phase entry (fig. 2c). A slight, but statistically insignificant, trend towards reduced G1 and elevated S phases upon the addition of estrogen to doxorubicin treatment (fig. 2b, c, +Dox bars) and the differences in the temporal nature of the assays may explain the apparent...
Fig. 3. Prolonged levels of estrogen alter the protein levels and increase specific phosphorylation of estrogen-signaling molecules. MCF-7 cells, cultured for 72 h in the presence or absence of estrogen, were lysed and analyzed by Western blotting. Within each panel, the Western blots are representative of nine or more experiments that were quantitated and shown in the graph. For each graph, the untreated control was set to 1, and the estrogen-treated group was expressed as the mean fold change of the untreated control ± SEM, as described in Materials and Methods. * Indicates statistical significance between groups treated with and without estrogen (p ≤ 0.05). a Androgen receptor protein levels increased with estrogen treatment. b Estrogen enhanced PI3K protein levels. c ER-α levels (black bars) were reduced by estrogen treatment, even as specific phosphorylations at ER-α S118 (dark grey bars), ER-α S167 (light grey bars), and ER-α Y537 (white bars) were elevated. d MNAR (black bars) and c-Src (grey bars) protein levels decreased with estrogen treatment, but the specific phosphorylation of c-Src’s activating tyrosine (c-Src pY418, white bars) was increased. e EGFR (black bars) and HER2 (grey bars) levels were reduced, but HER2-specific phosphorylation at Y877 (white bars) was enhanced with estrogen exposure.

Differences in proliferation/cell cycle progression between the growth and cell cycle assays. These data indicate that a sub-apoptotic doxorubicin concentration can cause cell cycle blocks that estrogen cannot fully overcome.

Prolonged Estrogen and/or Doxorubicin Treatment Causes Changes in Levels and/or Phosphorylation Status of Estrogen-Signaling Molecules

To gain insight into the effects of the various doxorubicin/estrogen treatments on molecules known to be involved in estrogen signaling, lysates from treated cells were analyzed by Western blotting for total protein levels or specific phosphorylations. Our first analyses were carried out on cells stimulated long-term with estrogen alone and compared to those maintained under hormone-deprived, or non-treated, conditions. Figure 3 shows that when compared to hormone-deprived controls, prolonged estrogen treatment alone caused accumulation of AR (fig. 3a) and PI3K (fig. 3b) proteins, both of which have been shown to mediate estrogen-induced proliferation and/or survival [37, 38]. Reduction of ER-α (fig. 3c), c-Src (fig. 3d), MNAR (fig. 3d), EGFR (fig. 3e), and HER2 (fig. 3e) protein levels was also observed. Changes to these levels may be the result of rapid protein turnover, a hallmark of active signaling, and/or reduced gene expression [39, 40]. In addition, specific phosphorylations associated with increased activity on ER-α (fig. 3c), c-Src (fig. 3d), and HER2 (fig. 3e) were elevated, similar to that seen with acute estrogen action [41–44]. Online supplementary data 2 (−Dox bars) provides the quantification of these and other effects on ER-β and ERK 1/2 proteins and on AR and ERK 1/2 phosphorylations, which were modestly or insignificantly altered by prolonged estrogen treatment.

The finding that 25 nM doxorubicin could induce a G1 block in the presence of estrogen suggested that extended doxorubicin treatment could affect estrogen downstream signaling (fig. 2c). Given that low levels of doxorubicin...
alone also caused cell cycle arrest (fig. 2b), we asked whether molecules involved in estrogen signaling were affected by doxorubicin treatment in the absence of estrogen. Cell lysates were analyzed by Western blotting following treatment with 25 nM doxorubicin to study these molecular effects. Figure 4 shows that in the absence of estrogen, prolonged doxorubicin treatment resulted in increases in AR (fig. 4a), ER-α (fig. 4a), EGFR (fig. 4b), and HER2 (fig. 4b) protein levels, an effect that is opposite to that of prolonged estrogen-alone treatment (with the exception of AR, whose protein levels were elevated by both treatments; fig. 3). See also online supplementary data 2 (–E, compare –Dox to +Dox), which additionally indicate a small but significant reduction in ER-α pS167 levels. These results indicate that doxorubicin alone can have effects on proteins involved in estrogen signaling that are antagonistic to the effects of estrogen alone.

Results depicted in figures 3 and 4 indicate that estrogen and doxorubicin individually affect estrogen-signaling molecules, but little is known about the signaling changes that occur when an estrogen-responsive tumor is treated with doxorubicin in the absence of estrogen suppression. To determine the molecular effects of doxorubicin on breast cancer cells cultured in conditions reflective of the human microenvironment, levels and phosphorylation states of proteins from estrogen-exposed cells were compared to those treated with both estrogen and doxorubicin. Surprisingly, doxorubicin and estrogen co-treatment augmented several estrogen-alone responses (fig. 3, 5). In comparison to estrogen alone, doxorubicin plus estrogen modestly but significantly increased AR protein levels (fig. 5a), increased HER2-specific phosphorylation (fig. 5d), and reduced MNAR protein (fig. 5b). In contrast, dual doxorubicin/estrogen treatment modestly reduced estrogen-alone-induced increases in PI3K levels (fig. 5c). However, doxorubicin did not affect many estrogen-alone-stimulated changes, including those to ER-α, c-Src, and EGFR protein levels and ER-α and c-Src phosphorylations (see online suppl. data 2 for quantitative comparisons of protein and phosphorylation levels between groups treated with and without doxorubicin on an estrogenic background (–Dox +E vs. +Dox +E)). Contrary to expectations, these results suggest that although doxorubicin had a slight detrimental effect on estrogen signaling (with respect to PI3K), it also left unaffected and even enhanced other aspects of the estrogen-signaling pathway.

In addition to chemotherapy, some patients with ER+ tumors are candidates for adjuvant estrogen ablation therapy. To better understand the molecular changes that occur when ER+ breast tumors are treated with chemotherapy in the presence or absence of estrogen suppression, we compared cells exposed to doxorubicin with and without estrogen treatment. Figure 6 and online supplementary data 2 show that compared to doxorubicin alone, co-treatment with estrogen resulted in increased AR (fig. 6a) and decreased ER-α (fig. 6b), MNAR (fig. 6c), c-Src (fig. 6d), EGFR (fig. 6d), and HER2 (fig. 6d) protein levels, consistent with changes seen with estrogen alone (fig. 3). We also observed increased specific phosphorylation at residues correlated with ER-α (fig. 6b), c-Src (fig. 6c), and HER2 (fig. 6d) activation, indicating active estrogen signaling in the presence of doxorubicin. Together, these data indicate that a low dose of doxorubicin cannot completely suppress estrogen signaling in estrogen-responsive breast cancer cells.

**Inhibitors of Estrogen-Signaling Molecules Reduce MCF-7 Cell Growth in Doxorubicin-Dependent and -Independent Manners**

The biochemical studies depicted in figures 3–6 and summarized in online supplemental data 2 clearly dem-

this end, various combinations of doxorubicin, estrogen, and inhibitors of the ER(s), SFK family, EGFR, PI3K, MEK, AR, and MMP proteins were tested for their net effects on MCF-7 cell proliferation. Figure 7 shows that neither PD-98059, a MEK inhibitor, nor GM 6001 (Gailardin), a pan-MMP inhibitor, significantly affected cell number in the absence of estrogen whether doxorubicin was present or not (fig. 7a, b, bars 1 vs. 3, and 5). However, in the presence of estrogen, the MEK inhibitor alone reduced cell number (fig. 7a, bar 2 vs. 4), an effect that was significantly augmented by doxorubicin (fig. 7a, bar 4 vs. 8). The MMP inhibitor, on the other hand, had little effect on cell number in the absence of doxorubicin and presence of estrogen (fig. 7b, bar 2 vs. 4) but significantly enhanced the cytotoxic effect of doxorubicin when estrogen was present (fig. 7b, bar 6 vs. 8) or not (fig. 7b, bar 5 vs. 7). When administered in the presence of estrogen, the addition of doxorubicin to the MEK and MMP inhibitors resulted in a statistically significant reduction in net proliferation (35.6 and 37.8% reduction, respectively; bars 4 vs. 8). Of all the tested inhibitors, only PD-98059 and GM 6001 exhibited this cooperativity with doxorubicin to reduce cell growth. These results suggest that therapeutically targeting MEK and MMP molecules in doxorubicin-resistant ER+ breast cancers is worthy of further investigation.

In contrast to the MEK and MMP inhibitors, the remainder of the tested targeted drugs acted largely independently of doxorubicin. Figure 8 shows that fulvestrant (Faslodex; an ER-α- and ER-β-targeted drug, fig. 8a) and gefitinib (Iressa; an EGFR inhibitor, fig. 8b) inhibited estrogen responses to nearly the same extent in the presence or absence of doxorubicin (bars 4 vs. 8 in each panel). Similar responses were seen with SU6656 (a SFK inhibitor, online suppl. data 4A) and LY 294002 (a PI3K inhibitor, online suppl. data 4B) as with fulvestrant; these three drugs showed the strongest inhibition of estrogen responses. Bicalutamide (Casodex; an AR-targeted drug, online suppl. data 4C) additionally demonstrated doxorubicin-independent inhibition, though its effects and mechanism of action are less well understood (see Discussion and online suppl. data 5).

While it was known that the ER, EGFR, SFKs, PI3K, and AR mediated estrogen-induced proliferation/survival of ER+ breast cancer cells [35, 37, 45, 46], the efficacy of their inhibitors in the presence of doxorubicin and estrogen had not previously been tested. These findings indicate that the ER protein(s), SFK protein(s), and PI3K are critical to tumor cell growth in the presence or absence of doxorubicin and could be exploited as therapeutic targets in treating doxorubicin-resistant breast cancer cells.

Fig. 5. A low concentration of doxorubicin has both positive and negative effects on estrogen signaling. MCF-7 cells were treated as depicted in figure 1, lysed, and analyzed by Western blotting. Within each panel, the Western blots are representative of the nine or more experiments that were quantitated in the graph. Estrogen-treated groups are expressed as the mean fold change of negative effects on estrogen signaling. MCF-7 cells were treated with proteins involved in estrogen signaling, whether doxorubicin was administered with or without estrogen. Given these alterations, we sought to determine if targeted inhibitors of estrogen effectors would improve the cytotoxic effects of doxorubicin in the presence of estrogen. To
Discussion

In clinical practice, 75% of breast tumors are classified as ER+ by immunohistochemistry (using a 1% positive staining cutoff), and many of the tumors with poor prognostic features are treated with a chemotherapy regimen likely to contain an anthracycline such as doxorubicin [47]. However, several studies have demonstrated that chemotherapy is less effective in patients with tumors that are ER+ than ER− [5]. This finding suggests that some mechanism(s) limit(s) chemotherapy-induced apoptosis or cytostasis, including perhaps estrogen signaling itself. However, many in the clinical community have avoided concomitant treatment of ER+ breast cancer with chemotherapy and inhibitors targeting estrogen-signaling molecules based on the rationale that estrogen promotes cell cycling and, therefore, chemotherapeutic efficacy [48]. This appeared to be confirmed by clinical findings in ER+ patients that the efficacy of tamoxifen (an ER-targeted drug) was not improved by concurrent exposure to chemotherapy [49, 50]. A closer examination of the seminal in vitro study supporting these conclusions raises ques-

Fig. 6. Estrogen signaling persists in the presence of doxorubicin. MCF-7 cells were treated according to the scheme depicted in figure 1. Following lysis, proteins were analyzed by Western blotting, as represented in the upper portion of each panel. Graphs depict the quantitations of the eight or more experiments. The doxorubicin-treated groups with and without estrogen were expressed as the mean fold change of the untreated control ± SEM, as described in Materials and Methods. * Indicates statistical significance between the estrogen-treated groups with and without doxorubicin (p ≤ 0.05). a As compared to doxorubicin alone, co-treatment with estrogen and doxorubicin increased AR levels. b The addition of estrogen to doxorubicin decreased ER-α protein (black bars) but increased specific phosphorylation at S118 (dark grey bars), S167 (light grey bars), and Y537 (white bars). c MNAR (black bars) and c-Src (grey bars) protein levels were decreased, while specific phosphorylation at c-Src Y418 (white bars) was increased from doxorubicin alone by co-treatment with doxorubicin and estrogen. d As compared to doxorubicin alone, EGFR (black bars) and HER2 (grey bars) protein levels were reduced, but specific phosphorylation of HER2 Y877 (white bars) was increased by the addition of estrogen to doxorubicin treatment.
tions as to its usefulness for informing clinical practice: the in vitro experiments demonstrating antagonism between estrogen treatment and chemotherapy involved super-physiological estrogen stimulation, as estrogen was added in the presence of serum [48], potentially resulting in abnormal proliferation properties and responses to chemotherapy. These findings are contrasted by those summarized in a meta-analysis of 194 breast cancer trials: there was a measurable trend towards increased disease-free and overall survival in ER+ and ER status-unknown subjects given concurrent versus sequential treatment with chemotherapy and tamoxifen [51]. Additionally, a recent small, single-arm study in advanced breast cancer patients treated them concurrently with anthracycline-based
chemotherapy and an aromatase inhibitor, which blocks estrogen production [52]. The regimen was well tolerated and 87% of the patients experienced clinical benefit over the course of the trial, supporting the rationale that concomitant estrogen-signaling inhibition and chemotherapy may positively affect clinical outcomes. The limited scope of the clinical trials studying concomitant treatment (i.e. before the era of modern chemotherapy regimens, aromatase inhibitors or other targeted inhibitors) [49, 50] leaves the field of combined chemo-endocrine therapy ripe for the further investigation of modern combinatorial regimens and novel molecularly targeted drugs.

Given that several studies working within a physiological range of estrogen have shown that doxorubicin is less effective in the presence of estrogen and given the availability of targeted inhibitors to mediators of estrogen signaling, we hypothesized that molecules involved in the estrogen response may mediate doxorubicin resistance and their inhibition during chemotherapy may improve patient outcomes. Therefore, we sought to define specific alterations in estrogen-signaling molecules that occurred in response to chemotherapy (doxorubicin in this study) alone or together with estrogen, so as to identify druggable targets for the improvement of chemotherapeutic outcomes of patients with ER+ tumors. Our study demonstrated that in the presence of estrogen, sub-apoptotic levels of doxorubicin (similar to those found intratumorally and in sera of treated patients) permitted and, in some cases, enhanced changes in a subset of estrogen-signaling molecules that estrogen alone induced. Furthermore, inhibiting many of these same molecules augmented the anti-proliferative effect of doxorubicin, suggesting that several mediators of estrogen signaling, including ER, c-Src, PI3K, MEK, and MMP proteins, limit the cytotoxic effects of doxorubicin and are thus promising therapeutic targets to be used in combination with the drug.

Although high levels of doxorubicin are administered to patients, the intratumoral concentration of the drug has not been reported. However, Hunz et al. [13] have shown intratumoral levels of epirubicin, an analog of doxorubicin with highly similar properties, to be in the range of 1–50 nM in breast cancer patients 24 h after being given a 90 mg/m² dose. Additional evidence suggests that intratumoral concentrations of doxorubicin may be quite low, including the rapid reduction in serum concentrations that occurs within hours of its administration [8–12] and the poor apoptotic responses of doxorubicin-treated ER+ breast tumors [3–5]. Furthermore, since anti-estrogen therapy is not administered concurrently with chemotherapy in clinical practice, most breast cancer patients receiving adjuvant chemotherapy are exposed to physiologic levels of estrogen at the time of its administration (post-menopausal patients have low, but measurable, serum estradiol levels and higher intratumoral estradiol levels). Based on these treatment paradigms, our cell culture assays initially tested estrogen responses to a range of doxorubicin concentrations from 0 to 1 μM. Our data demonstrated that in ER+ cell lines, estrogen can induce proliferation in the presence of doxorubicin at concentrations of ≤100 nM (fig. 2 and data not shown). Within this range, doxorubicin reduced the proliferative effect of estrogen alone by causing G1 accumulation and reduced S phase entry but did not induce apoptosis, which is consistent with clinical observations of estrogen-responsive tumors treated with chemotherapy. These cell culture studies provide rational support of the hypothesis that estrogen response may mediate doxorubicin resistance and their inhibition during chemotherapy may improve patient outcomes.
that very low intratumoral concentrations of chemotherapy coupled with an estrogenic environment may explain the poor pathologic complete response rates of ER+ tumors treated with chemotherapy alone. We speculate that within a tumor, most cells may arrest in the presence of doxorubicin, but some resume estrogen-induced proliferation as doxorubicin levels drop.

The results shown in figure 3 and online supplementary data 2 demonstrated that ER+ cancer cells subjected to prolonged estrogen elicited similar molecular responses to those described for brief estrogen treatments [28, 39, 53–56]. Though we chose to focus on changes in members of the rapid estrogen-signaling pathways in this study, transcriptional changes have also been reported to occur within hours of estrogen stimulation [57]. Indeed, the ER-α, AR, EGFR, and HER2 protein level fluctuations that we observed under the various treatment paradigms are consistent with estrogen-regulated, ER-α-mediated transcriptional mechanisms that have been described previously following several days of estrogen exposure [39, 40, 58–60]. However, we speculate that regulation of protein turnover may also play a role in altering levels of the various signaling molecules, such as occurs when phosphorylation of Ser118 targets ER-α for proteasomal degradation [61]. Whether transcriptional or post-transcriptional/translational modification mechanisms are at play, overall, prolonged estrogen exposure mirrored pro-proliferation and pro-survival responses stimulated by shorter courses of estrogen.

Interestingly, doxorubicin was found to suppress estrogen-signaling pathways when administered alone (fig. 4). The upregulation of ER-α, EGFR, and HER2 levels that occurred in the presence of doxorubicin was opposite of estrogen’s effect on these molecules, suggesting that doxorubicin may antagonize ER pathway signaling. Furthermore, doxorubicin-induced upregulation of ER-α and AR correlated with cell cycle arrest (fig. 2c, 4a), suggesting that the upregulation of the AR may have facilitated a doxorubicin response. These results mimic those in patients with ER+ breast cancers that co-express the AR and ER, as they are reported to have better survival outcomes [62] than AR-negative patients when treated with chemotherapeutic or endocrine therapies.

Doxorubicin-induced changes, however, were counteracted by the addition of estrogen. As shown by the increased phosphorylations and protein level modulations in figure 6, doxorubicin was unable to prevent estrogen signaling, even enhancing it in some instances (fig. 5, 6). Furthermore, associations between c-Src and ER-α that are described as supporting estrogen signaling within minutes of stimulation [29] were altered in much the same way as with estrogen treatment alone (online suppl. data 3). On a molecular level, these data demonstrated that low levels of doxorubicin do not completely ablate estrogen signaling.

When comparing estrogen effects to those resulting from dual treatment with estrogen and doxorubicin, doxorubicin was shown to have little effect on estrogen-alone signaling, as described above. For example, doxorubicin plus estrogen modestly enhanced AR and MNAR protein levels and HER2-specific phosphorylations over those seen with estrogen alone, while reducing increases in PI3K levels (fig. 5). However, despite the negative impact of doxorubicin on proliferation (as seen in fig. 2c, d, 7, 8, and online suppl. data 4), most specific phosphorylation levels and pro-proliferative protein-protein interactions of estrogen-signaling effectors were maintained at estrogen-alone levels (online suppl. data 2 and data not shown). Based on these findings, we speculate that within a physiologic system, cells treated with doxorubicin in an estrogenic environment are molecularly poised to participate in robust estrogen signaling upon the removal of doxorubicin.

Previous small-molecule inhibitor studies had identified mediators of growth and survival in ER+ breast cancer cells but had not considered their effects in the context of estrogen and chemotherapy together [37, 38, 63]. Our findings (fig. 7, 8, and online suppl. data 4) provide rationale for targeting the canonical ER proteins themselves, the SFK proteins, PI3K, MEK, and/or EGFR in patients treated with doxorubicin. In our study, the most robust inhibition of proliferation and survival was demonstrated by fulvestrant, SU6656, and LY 294002, the respective inhibitors of ER(s), SFK proteins, and PI3K. These inhibitors have all shown efficacy as single agents in inhibiting growth and survival in ER+ cell lines [54, 63–65]; however, monotherapies (except AIs and fulvestrant) to date have all failed in preclinical xenograft models or clinical trials for ER+ tumors [66–69]. For this reason, we suggest that outcomes may be improved with combinatorial treatment of targeted therapies with one another or with chemotherapeutic agents. Fulvestrant, gefitinib, LY 294002, and dasatinib, a kinase inhibitor that targets the SFK proteins, have all shown promising results when combined with doxorubicin in ER+ breast cancer cell culture and/or xenograft studies [6, 70–72]. Furthermore, a recent report demonstrated that 82% of advanced cancer patients treated with concurrent gefitinib and liposomal doxorubicin experienced clinical benefit over the course of the study [73].
study nor in vitro work on cardiomyocytes suggest that the addition of the tested inhibitors would increase the cardiotoxicity inherent to anthracycline-based chemotherapy [73, 74], though this has yet to be tested directly in large clinical trials. Together, these data imply that ER, SFK proteins, PI3K, MEK, and/or EGFR inhibitors may improve clinical outcomes when combined with chemotherapy.

Inhibition of MEK and MMP proteins showed less anti-proliferative efficacy when administered alone than did inhibitors of ER, SFKs, and PI3K, but nevertheless were able to enhance the cytotoxic effect of doxorubicin in the presence of estrogen (fig. 7), suggesting that these enzymes may also play important roles in MCF-7 cell resistance to doxorubicin. Work in sarcoma and rat neuronal cells showed that MMP-7 and MMP-3 inhibit doxorubicin action by negatively regulating Fas action, a mechanism that may also be operative in ER+ breast cancer [75, 76]. We speculate that the modest effect of the MMP inhibitor may be due to its broad spectrum of action and its ability to simultaneously inhibit pro-proliferative and anti-proliferative MMPs [77, 78]. Similarly, the multiple functions of the MEK/MAP kinase pathway can give rise to contrasting outcomes following its inhibition, which appear to depend on cellular context [79–81].

From our studies, the role of the AR in mediating estrogen-induced proliferation and survival was less clear. Inhibition of cell proliferation following treatment with bicalutamide indicated AR involvement in estrogen action (online suppl. data 4C). Bicalutamide has been shown to downregulate the AR and inhibit its transcriptional activities in prostate cancer cell lines [82, 83]. However, we found that bicalutamide behaved differently in ER+ MCF-7 and T47-D cells than in LNCaP prostate cancer cells (online suppl. data 5 and data not shown). For example, in ER+ cell lines cultured in the presence of estrogen, the drug had no effect on AR levels or phosphorylation, while in the absence of estrogen, bicalutamide increased both. We also demonstrated through AR knockdown that the AR was not necessary for estrogen- or doxorubicin-dependent changes in proliferation or growth. Together, these data suggested that in ER+ breast cancer the AR level may be enhanced, but appears not to be necessary for estrogen-induced proliferation.

In summary, we describe doxorubicin-induced changes on estrogen signaling and show that estrogen signaling is indeed relevant to chemotherapeutic efficacy. We demonstrated the surprising finding that in the presence of estrogen, the MCF-7 breast cancer cell line responded to sub-apoptotic levels of doxorubicin (which may occur intratumorally) by enhancing estrogen-stimulated changes in phosphorylation and protein levels of a subset of estrogen-signaling molecules. Further, the negative effects of doxorubicin alone correlated with suppression of the estrogen-signaling pathway (fig. 9). These findings provide rationale for targeting estrogen/ER effector proteins to enhance chemosensitivity of ER+ tumors. Such dual therapy may ultimately improve outcomes for patients with ER+ breast tumors receiving chemotherapy. Only a few clinical trials have been conducted combining conventional chemotherapy with targeted therapy aimed at estrogen signaling-related molecules in the ER+ setting, though the success of HER2-targeted therapy combined with chemotherapy validates such an approach [84, 85]. Our study indicates that the addition of drugs targeting the ER, EGFR, the SFKs, MEK, PI3K, and/or the MMP proteins to a conventional chemotherapy regimen may improve chemosensitivity. Additionally, it appears that in vitro doxorubicin treatment of ER+ breast cancer is superior when administered in the absence of estrogen. Clinically, this supports the design of combination chemoendocrine clinical trials, several of which are ongoing.
