Abstract

We report on a 62-year-old Chinese male patient who presented with a pigmented lesion in the umbilical area and who was treated for omphalitis in a local hospital for 1 month. Biopsy pathological examination revealed that the lesion was a melanoma. The Breslow depth was estimated at 3 mm, and Clark's level was IV. Ultrasonography showed no suspicious pathological lymph nodes, and no metastases were detected in the lung, liver or brain through CT scans. Reexcision was performed with lateral margins >2 cm from the original scar down to the peritoneum, including the umbilicus, round ligament of the liver and urachus. No adjuvant therapy was suggested, and the patient was still alive without recurrences or metastases after 36 months.

Background

Melanoma is one of the most common cutaneous malignancies in the world. Over the past decades, melanoma-associated morbidity has been steadily increasing. Melanoma often occurs in sun-exposed areas of the skin in white populations, such as the upper back in men and the back and lower legs in women [1]. The most common site of cutaneous melanoma in non-white populations (such as the Chinese) is the feet [2]. However, melanoma arising in the umbilicus is extremely rare. Here, we report a case of primary umbilical melanoma, whose proper treatment was delayed for 1 month because of misdiagnosis.

Case Presentation

A 62-year-old Chinese male patient presented with a 1-month history of a pigmented lesion in the umbilical area. He noticed the brown nevus 4 years before examination. Until 1 month prior to examination, there was no obvious change of the nevus, but then it gradually grew larger and produced discharge. For 1 month, the patient was treated for omphalitis with antibiotics in a local hospital – without success. Subsequently, he was referred to the oncology outpatient clinic of our hospital. Physical examination revealed a brown lesion sized 2 × 1 cm with an irregular border on the vertical sidewall of the umbilicus. Neither visible satellite lesions nor palpable superficial pathological lymph nodes were detected. Excision biopsy was performed with 1 cm margins beyond the border of the lesion. Pathological examination revealed that the lesion was a malignant melanoma. The Breslow depth was estimated at 3 mm, Clark's level was IV (fig. 1a) and tumor mitotic rate ≥6 mitoses/mm² (fig. 1b). Ultrasonography of the axillary and groin areas revealed no suspicious pathological lymph nodes, and no metastases were detected in the lung, liver or brain through CT scans. A wide, irregular reexcision was subsequently performed with lateral margins >2 cm (fig. 2a) from the original scar down to the peritoneum, including the umbilicus, round ligament of the liver and urachus (fig. 2b). We concluded the procedure by closing the abdominal cavity and incision directly (fig. 2c). No adjuvant therapy was suggested after surgery excision, and the patient has remained disease-free in the 36 months since surgery.

Discussion

For several reasons, diagnosis of navel melanoma is usually delayed. First, the umbilicus is a hidden area, and therefore tumors are not easy to detect for patients and doctors, especially in overweight patients. Second, primary melanomas originating from the umbilicus are extremely rare, and doctors lack the knowledge of both diagnosis and treatment. In 1916, Cullen [3] reported 3 presumed cases of umbilical melanoma. Since then, only 13 cases have been reported in the literature. In 1965, Steck and Helwig [4] collected a large series of 112 umbilical tumors and reported 4 cases of primary melanomas. In addition to Steck and Helwig's work [4], only 9 other individual cases are reported in the literature [5–12]. About half of these cases developed from a preexisting nevus [4–12], which is similar to our case.

Our patient was misdiagnosed with omphalitis and treated with antibiotics for 1 month. Based on this experience, careful follow-up examinations are highly suggested in patients with umbilical nevus and omphalitis. If special changes such as an increase in size or diabrosis on the surface are observed, surgery excision (even a prophylactic excision) should be considered early to determine if the patient has umbilical melanoma, even if it appears only to be omphalitis [10].

The treatment of umbilical melanoma is also difficult because of the complex anatomy of the umbilicus [9]. After delivery, the umbilical cord retains some ligaments connecting the umbilicus to the peritoneum and intraabdominal visceral organs such as the bladder and liver. Accordingly, it is possible that umbilical melanoma grow into and along these fibrous remnant attachments. Local recurrence was reported due to remaining melanoma cell nests in the omphalomesenteric duct [9]. We performed a surgical excision down to the peritoneum, including the umbilicus, round ligament of the liver and urachus to eliminate possible melanoma cell remainings.

Reconstruction of the navel region has been previously reported after surgical excision [13–15]. However, sometimes it is a difficult procedure to perform because of the wide excision necessary to remove the cancerous material, as was the case with our patient. Therefore, we used an irregular "T"-shape incision, which can reduce the tension of the abdominal wall and allows easy placement of sutures within the abdominal cavity.

Due to its low incidence, the efficacy of sentinel lymph node biopsy in primary malignant umbilical melanoma is still ambiguous [12]. As no suspicious regional lymph node metastasis was detected with ultrasonography, sentinel lymph node biopsy was not routinely performed in our patient.

After a 36-month follow-up, there were no suspicious local recurrences or metastases to the regional lymph nodes, and ultrasound testing of the abdominal wall around the incision, axillary and groin lymph nodes was negative as well.

Primary umbilical melanoma is rare, and therefore surgeons should keep in mind that follow-up examinations of patients with umbilical nevus and omphalitis are very important. To treat an umbilical melanoma, clear, deep and lateral margins are necessary. Excision of the entire umbilicus, including its attachment to the peritoneum, is recommended, and in some cases, reconstruction of the navel region can be performed.
