Abstract

We present an unusual case of spontaneous regression of hepatocellular carcinoma (HCC). A 77-year-old man with alcoholic liver cirrhosis presented with a 50-mm tumor in the Couinaud's segment 8 (S8) of the liver, a 15-mm tumor in the S8-7 and 10-mm tumors in the other segments (S4, S6). The tumors were diagnosed as HCC by typical imaging findings and elevated serum alpha-fetoprotein (AFP, 1,825.0 ng/ml) and protein induced by vitamin K absence II (PIVKA II, 3,043 mAU/ml). One month later, AFP and PIVKA II decreased to 51.1 ng/ml and 411 mAU/ml, respectively, and the 50-mm tumor in the S8 became small and completely necrotic on angiography and computed tomography arteriography without any treatment. On the other hand, the 15-mm tumor in the S8-7 decreased in size to 10 mm and received blood supply from the right posterior superior arteries (A7). The other 10-mm tumors remained. Ischemia of the tumors due to disruption of the feeding artery (A8) might have induced tumor regression in the present case.

Introduction

Spontaneous regression (SR) of malignant tumor was first defined by Cole and Everson [1] as complete or partial clearance of malignant cells in the absence of any specific treatment, particularly antineoplastic chemotherapy or surgical resection. It is an extremely rare phenomenon and its incidence is estimated to be one per 60,000–100,000 cancer patients [2]. SR of malignant tumor has been reported mainly in neuroblastoma, renal cell carcinoma, malignant melanoma, malignant lymphoma, and leukemia. SR of hepatocellular

carcinoma (HCC) is an infrequent phenomenon. We report an unusual case of SR of HCC, possibly due to disruption of the feeding artery.

Case Report

A 77-year-old man with alcoholic liver cirrhosis was referred to our hospital on August, 2010 for workup of hepatic masses incidentally found by abdominal computed tomography (CT). He had no history of hypertension, diabetes mellitus, and atherosclerosis. He had been a regular drinker, consuming approximately 120 g/day of alcohol every day for 50 years. He had smoked 20 cigarettes per day for 50 years. He took no drugs.

Examination of the head, neck, chest, heart, and extremities was unremarkable. Palmar erythema and vascular spider were noted in the skin. The abdomen was soft and flat, and neither masses nor ascites were palpable. Laboratory examinations showed Hb of 9.5 g/dl, platelets of 139,000/mm³, and WBC count of 6,600/mm³. Blood chemistry tests revealed aspartate aminotransferase of 172 IU/l, alanine aminotransferase of 59 IU/l, γ -GTP of 461 IU/l, alkaline phosphatase of 461 IU/l, albumin of 2.9 g/dl, globulin of 3.9 g/dl, total bilirubin of 2.6 mg/dl, prothrombin time of 51.7%, and glucose of 102 mg/dl. Serum HBs antigen, HBs antibody, and HCV antibody were negative. Serum alpha-fetoprotein (AFP) was 1,825.0 ng/ml (normal <10 ng/ml) and protein induced by vitamin K absence II (PIVKA II) was 3,043 mAU/ml (normal <40 mAU/ml). His Child-Pugh score was 8 (Child-Pugh class B).

Abdominal ultrasonography demonstrated a 50-mm hypoechoic mass with a mosaic pattern in the right anterior superior segment of the liver (Couinaud's segment 8, S8) and a 15-mm hypoechoic mass in the S8-7. Dynamic contrast-enhanced CT scan showed a partially hypervascular tumor with necrotic area in the S8 and a hypervascular tumor in the S7-8 (fig. 1) and 10-mm hypervascular tumors in the other segments (S6 and S4) on August, 2010. The findings of the above high level of tumor markers and imaging examinations were consistent with HCC. He did not receive any further treatment for HCC including herbal medicine and stopped drinking alcohol for one month after the diagnosis of HCC. There had been no accidental events including fever and pain for several months. One month after the diagnosis, AFP and PIVKA II spontaneously decreased to 51.1 ng/ml and 411 mAU/ml, respectively. The 50-mm mass in the S8 decreased to 30 mm and became completely necrotic on CT arteriography (CTA) (fig. 2) on September, 2010. The 15-mm mass in the S8-7 diminished to 10 mm and was described as an enhanced lesion on CTA (fig. 2). Hepatic angiography disclosed no tumor stain and occlusion in the right anterior superior arteries (A8) (fig. 3a, b). Tumor stains were noted in the A7 (the above mass in the S8-7) (fig. 3c), A6, and A4. The hypervascular tumors were treated by transcatheter arterial chemoembolization (TACE) using an emulsion of 3 ml lipiodol and 30 mg epirubicin with gelfoam. Serum AFP and PIVKA II decreased to the normal range (5.7 ng/ml and 37 mAU/ml, respectively) on October, 2010.

Unfortunately, the tumor regression was not confirmed histologically. After that, the tumor with SR in the S8 completely became scar without local recurrence. Six and 16 months after the first treatment, several new recurrent tumors that measured 10 mm were detected in the other segments of the liver. TACE was performed to the recurrences. AFP and PIVKA II have remained normal in spite of the recurrences.

Discussion

We report herein a rare case of SR of HCC. For diagnosis of SR, it is important to prove the presence of malignant cells morphologically. The limitation of the present case study is that this case was not histologically proven before SR. However, the findings of the abdominal CT (fig. 1, fig. 2) and the marked elevation of serum AFP and PIVKA II level were useful for the diagnosis of HCC.

In the previous reports of SR of HCC, clinical characteristics vary widely. Tumor regression, either partial or complete, has been reported in various patients. There has been no common tendency about the number and size of tumor, the level of tumor markers, extrahepatic metastases, and causative liver disease [3]. The causative factors and mechanisms leading to SR of HCC are unclear, although two possible causes have been considered in previous literature [4].

In the first place, ischemia has been thought to be the major cause of subsequent necrosis of the oxygen-sensitive malignancy. Because of the hypervascular nature of HCC, an important factor might be an insufficient blood supply to the tumor, possibly due to disruption of the feeding artery [5, 6], portal vein tumor thrombus [7, 8], deprivation of oxygen due to rapid natural tumor growth [8], massive bleeding [9], and poor arterial supply in cirrhotic liver [10].

In the second place, immunological mechanisms might cause SR of HCC. Abstinence from alcohol or smoking [8, 11], blood transfusion [12], the use of some herbal medicine [13], withdrawal of anabolic steroids [14], and fever [15] stimulate the production of cytokines such as tumor necrosis factor (TNF) and TNF may play an important role in antitumor activities. Tumor regression has been observed not only in the primary site but also in metastatic regions by systemic effects such as immune responses.

What are the causative factors leading to SR of HCC in the present case? Generally, SR of HCC develops after the above possible events; however, none of these events could be identified in the present patient. At the first diagnosis, the 50-mm tumor in the S8 was described as a high-, iso-, and low-density lesion at the early phase on dynamic-enhanced CT. At this time, the tumor in the S8 might have already begun to lose arterial blood (A8) and to become necrotic. One month later, the tumor in the S8 spontaneously became small and completely necrotic and the 15-mm tumor in the S8-7 decreased to 10 mm (fig. 1, fig. 2). Tumor stain was absent in the A8 (fig. 3a, b) and was present in the A7 (fig. 3c) on hepatic angiography. In addition, the tumors in the other segments (S6 and S4) remained the same in size and character. Therefore, disruption of only the feeding A8 may be responsible for this phenomenon. Namely, the tumor in the S7-8 might originally have received blood supply from the A7 and A8 and decreased in size, possibly due to disruption of the feeding A8.

Two mechanisms of local ischemia due to loss of arterial blood supply are speculated: disruption of the feeding artery associated with angiography [5] and arterial thrombosis [6]. The former is due to a case in which, during the procedure of superselective catheterization, severe subintimal injury occurred in the proper hepatic artery [5]. The latter is deduced from a case in which the resected specimen showed arterial thrombus in non-tumor liver tissue [6]. The present case is unique as regards the fact that CT suggested the concern of blood supply (A8) loss by the complete tumor regression in the S8 and the partial regression in the S7-8. However, it is difficult to prove the local effect of deficiency of blood supply (A8) in the present patient. Furthermore, the mechanisms which lead to disruption of the feeding A8 remain unknown. Thrombus might have been transiently formed only in the A8.

Abstinence from alcohol for one month might have improved his immunological function [11]. However, it is difficult to explain the phenomenon by systemic effect of the

immunological mechanisms, because the other tumors in the S6 and S4 remained. We assume that a local effect was involved in the mechanism of SR in the present patient.

After all, although the precise mechanism of SR cannot be fully explained in the present case, disruption of the feeding artery might have played a role in this outcome [6]. We consider that the accumulation of clinical data obtained from patients with SR of HCC will contribute to the understanding of this phenomenon.
