Abstract

We report on a 70-year-old woman with diffuse normolipemic plane xanthoma (DNPX) who developed macular yellowish patches on the eyelids, both cheeks, and the nose. Histology revealed the accumulation of CD68-positive foam cells and Touton giant cells in the superficial dermis. Plasma lipid levels were within normal limits. The patient had no underlying hematological diseases. Her extensive lesions precluded surgical excision. The patient was given oral probucol instead, which resulted in a significant reduction of the lesions after 2 weeks. The lesions almost disappeared within 8 months. Plane xanthoma is primarily treated with excisional or abrasive therapies; however, probucol can be a safe and effective alternative therapy for DNPX.

Introduction

Diffuse normolipemic plane xanthoma (DNPX) was first described by Altman and Winkelmann in 1962 [1]. The features of this entity are: (1) xanthelasma palpebrarum; (2) diffuse xanthoma planum of the head, neck, trunk, and extremities, and (3) plasma lipid values that are within normal limits. Several associations have been reported between DNPX and lymphoproliferative and myeloproliferative disorders, particularly multiple myeloma and benign monoclonal gammopathy (often IgA) [2, 3]. All therapeutic options for the treatment of plane xanthoma include mechanical removal by excision, chemabrasion, dermabrasion, or abrasive laser therapy [4–6]. We report on a patient with DNPX who received oral probucol and showed significant clearing of the lesions. We suggest that probucol be included as a primary therapy for DNPX.

Case Report

A 70-year-old woman presented with well-defined macular yellowish patches on her eyelids, both cheeks, and the nose lasting over a few years (fig. 1). She had no history of topical steroid use or extensive sun exposure on her face. Her medical history was unremarkable. A skin biopsy specimen revealed the accumulation of foam cells and Touton giant cells in the superficial dermis (fig. 2). These cells were CD68 positive, and CD1a and S-100 negative. Complete blood count, and liver and renal function tests were within normal limits, but she had elevated levels of IgA [460.7 mg/dl (normal values: 100–400 mg/dl)] and amylase [270 IU/l (normal values: 40–120 IU/l)]. No M protein was noted. Plasma lipid levels including total cholesterol, HDL and LDL cholesterol, triglycerides, and apolipoproteins were normal. Chest X-ray and abdominal ultrasonography were also normal. She was diagnosed with idiopathic macroamylasemia and treatment was considered unnecessary. Based on the clinical and histopathological findings, a diagnosis of DNPX was made and oral administration of probucol (500 mg/day) was initiated. The lesions began to recede after 2 weeks and had almost resolved within 8 months (fig. 3).

Discussion

DNPX, first described in 1962 [1], is characterized by diffuse, yellow to orange, slightly elevated plaques with sharply delineated borders that may affect any part of the body. Normolipemic cutaneous xanthoma can be categorized into 3 groups: type I–III. Type I contains patients with xanthomas found in association with an altered lipoprotein content or structure. Type II is associated with an underlying lymphoproliferative disease. Type III consists of patients with neither lipoprotein abnormalities nor underlying systemic disease, but in whom local tissue alterations seem to play a role in xanthoma formation [7].

Several therapeutic options exist for the treatment of plane xanthoma. Lesions can be removed by excision, chemabrasion, dermabrasion, or abrasive laser therapy [4–6]. Lorenz et al. [4] used an Er:YAG laser for full-face DNPX lesions under general anesthesia and reported that the lesions were almost completely removed after 2 sessions. Although these excisional or abrasive therapies may be useful for limited lesions including palpebral xanthelasmas, they may be too invasive for widespread lesions. In addition, a risk of scarring has been associated with these treatments. Therefore, another therapeutic option with medication may be warranted.

Probucol is an antioxidant that may inhibit atherogenesis by limiting the oxidative modification of LDL cholesterol [8, 9] and, thus, foam cell formation and/or endothelial cell injury [9]. It has been used for the treatment of hypercholesterolemia in some countries including Japan [8]. Harris et al. [10] showed that xanthelasma lesions decreased in size in their 7 cases, and 3 lesions disappeared during probucol therapy in patients with hypercholesterolemia. Furthermore, 17 out of 25 xanthelasma patients (68%) with normolipemia exhibited regression after taking probucol [11]. Therefore, we used probucol to treat our patient with DNPX. The results obtained were remarkable, and we suggest that probucol be included as a primary therapy for DNPX.
