Abstract

Pulmonary tumor embolism rarely occurs in epithelial-derived tumors, but it has been described in different tumor entities. Microscopic pulmonary tumor embolisms are often only discovered on autopsy. Pulmonary thromboembolism, on the other hand, is a frequent complication in cancer patients, and surgery in patients with a malignant tumor is an additional risk factor. The differential diagnosis between pulmonary thromboembolism and pulmonary tumor embolism can be challenging. In this case report, we describe the rare case of a patient with primary renal synovial sarcoma and the workup for a thrombus in the left pulmonary artery.

Case Report

We report the case of a 52-year-old man with synovial sarcoma of the right kidney. Laparoscopic nephroureterectomy was performed in January 2012, under the suspicion of renal cell carcinoma (fig. 1). The postoperative course was complicated by pulmonary

embolism. The patient was put on anticoagulant therapy with low-molecular-weight heparin.

Surprisingly, the histologic findings were compatible with synovial sarcoma, verified by the detection of the typical t(X, 18) translocation and the SYT/SSX fusion gene. The initial assessment confirmed stage III disease: pT2b (maximum tumor size 8.2 cm), Nx M0 V1 (formation of a tumor thrombus in the right renal vein) G3.

According to a meta-analysis published in 1997, adjuvant chemotherapy can prolong progression-free survival, and there is a trend towards prolonged overall survival [1]. Further prospective studies have evaluated this question, and in high-grade soft tissue sarcomas adjuvant chemotherapy can be considered [2]. Adjuvant chemotherapy was discussed with our patient and, bearing in mind the high risk of recurrence in this case (tumor size, histologic grading and angioinvasion), 4 cycles of adjuvant chemotherapy with doxorubicin and ifosfamide were applied [3]. At the end of the treatment visit, a CT scan was performed and no tumor could be detected, but there was still evidence of a pulmonary embolus in the left inferior lobe. Subsequently, the patient was kept on anticoagulant therapy with low-molecular-weight heparin.

At the first follow-up visit 4 months after the completion of adjuvant chemotherapy, there was still no evidence of local tumor recurrence or metastases; however, in the area of the left inferior lobe pulmonary artery, a persisting soft tissue formation of unknown etiology could be documented. This entity was deemed most likely to be scar tissue after thromboembolism with pulmonary infarction or residual thrombus.

In the further follow-up period 3 months later, a CT scan showed progression of this soft tissue formation with partial occlusion of the left inferior lobe pulmonary artery (fig. 2); no uptake could be shown on PET/CT (fig. 3). Subsequently, a bronchoscopy with endobronchial ultrasound-guided transbronchial needle aspiration was performed for tissue sampling of the endoluminal thrombus. Histology revealed a spindle cell proliferation, which was compatible with metastasis of the known synovial sarcoma. At this time, no other sites of active disease could be detected on CT. Following data favoring metastasectomy in isolated pulmonary metastasis in selected patients [4], a lobectomy of the left lower lobe with subsequent resection of the lingula and bronchoplasty were performed (fig. 4). Histology confirmed a synovial sarcoma metastasis (fig. 5).

Written informed consent was obtained from the patient for publication of this case report and any accompanying images. A copy of the written consent form is available for review from the editor of this journal.

Discussion

Synovial sarcomas account for approximately 5–10% of adult soft tissue sarcomas and most commonly arise in the proximity of large joints [5]. Primary renal sarcomas of any subgroup are a rare entity, but primary renal synovial sarcomas are extremely rare. To our knowledge, fewer than 70 cases have been mentioned in the literature since the first case was published in 2000 [6].

Malignant tumors in general carry an increased risk for thromboembolism; in addition, surgery is a known risk factor for pulmonary embolism or deep vein thrombosis. The risk varies and depends on cancer type and surgical intervention [7]. These facts explain why occurrence of pulmonary embolism shortly after surgery in a patient with synovial sarcoma did not raise any further suspicion.

In order to further explore the hypothesis that the persistence of a clot 3 months after the occurrence of pulmonary embolism could explain the soft tissue formation in the area of the left inferior lobe pulmonary artery in our patient, we reviewed the literature concerning the rate of clot resolution under anticoagulant therapy following pulmonary embolism. Based on our findings, we decided to continue with therapeutic anticoagulation. In a systematic review published in 2006, it was concluded that complete resolution of the pulmonary embolus is not achieved in over 50% of patients 6 months after the diagnosis of pulmonary embolism [8]. The authors themselves pointed to the limitations of their final conclusion: in the studies considered for the review, the duration of anticoagulation therapy differed considerably in length and timing related to the follow-up scans [8].

A more recent study, published in January 2013, which compared CT and perfusion scintigraphy in documenting clot resolution after 3 weeks of anticoagulant treatment for pulmonary embolism, demonstrated that complete clot resolution could be measured on CT in 44% of patients (a slightly smaller proportion when measured with scintigraphy) [9]. Since no data were collected after 4 or 6 months, this cannot be directly compared to the results published in the aforementioned review.

In conclusion, a residual perfusion defect and residual thrombus 4 months after starting anticoagulant therapy does not seem to be a rare event, even though in 44% of patients with pulmonary embolism complete clot resolution can be achieved after 3 weeks of anticoagulant therapy.

Pulmonary tumor embolism is a rather rare incident that occurs in different tumor entities, mainly in epithelial-derived tumors. Microscopic pulmonary tumor embolisms are more frequent, difficult to diagnose and often only discovered postmortem; however, they can result in pulmonary hypertension or even cor pulmonale [10]. A number of case reports address tumor embolisms in sarcomas in general [11, 12], some of which occurred in clear association with surgery. Another rare differential diagnosis for pulmonary embolism is primary pulmonary artery sarcoma [13]. To our knowledge, only 1 case of tumor embolism in synovial sarcoma has been published so far [14] and no cases in primary renal synovial sarcoma, specifically.

Independent of the primary tumor, the main problem remains differentiating between pulmonary thromboembolism and pulmonary tumor embolism. Since the latter, all in all, is a very rare event compared to the high incidence of pulmonary embolism from blood clots, it most likely will rarely be a straightforward diagnosis.

FDG-PET/CT may be a useful diagnostic tool to differentiate between thromboembolism and tumor embolism, owing to its high sensitivity of over 90% in detecting sarcomas [15]. The sensitivity in synovial sarcomas in particular is about 80%. However, as shown in our patient, a negative PET/CT scan does not exclude pulmonary tumor embolism, and a definitive diagnosis can only be made by means of pathologic tissue examination. The endobronchial ultrasound-guided transbronchial needle aspiration technique provides a new method to obtain tissue.

Conclusion

We would like to raise awareness to the possible differential diagnosis of pulmonary tumor embolism in cancer patients, especially when CT scans show atypical features or persisting perfusion defects despite appropriate anticoagulant therapy.
