Abstract
Background/Aims: Identifying the best method to estimate the glomerular filtration rate (GFR) in bariatric surgery patients has important implications for the clinical care of obese patients and research into the impact of obesity and weight reduction on kidney health. We therefore performed such an analysis in patients before and after surgical weight loss. Methods: Fasting measured GFR (mGFR) by plasma iothexol clearance before and after bariatric surgery was obtained in 36 severely obese individuals. Estimated GFR was calculated using the Modification of Diet in Renal Disease equation, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation using serum creatinine only, the CKD-EPI equation using serum cystatin C only and a recently derived equation that uses both serum creatinine and cystatin C (CKD-EPI_{creat-cystC}) and then compared to mGFR. Results: Participants were primarily middle-aged white females with a mean baseline body mass index of 46 ± 9, serum creatinine of 0.81 ± 0.24 mg/dl and mGFR of 117 ± 40 ml/min. mGFR had a stronger linear relationship with inverse cystatin C before (r = 0.28, p = 0.09) and after (r = 0.38, p = 0.02) surgery compared to the inverse of creatinine (before: r = 0.26, p = 0.13; after: r = 0.11, p = 0.51). mGFR fell by 17 ± 35 ml/min (p = 0.007) following surgery. The CKD-EPI_{creat-cystC} was unquestionably the best overall performing estimating equation before and after surgery, revealing very little bias and a capacity to estimate mGFR within 30% of its true value over 80% of the time. This was true whether or not mGFR was indexed for body surface area. Conclusions: In severely obese bariatric surgery patients with normal kidney function, cystatin C is more strongly associated with mGFR than is serum creatinine. The CKD-EPI_{creat-cystC} equation best predicted mGFR both before and after surgery.

Introduction
Bariatric surgery is a common and effective treatment for severe obesity, a problem of global proportions that is linked to a variety of adverse clinical outcomes [1]. Bariatric surgery is of interest to nephrologists not only because it is associated with an increased risk for both acute and chronic kidney injury [2] but also because it serves as a research model to investigate the relationship between obesity, weight reduction and kidney health. Investigations using the bariatric surgery model suggest that weight...
loss in obese persons may have renoprotective effects [3, 4], although the body of evidence relies primarily on estimated glomerular filtration rate (eGFR) rather than directly measured GFR (mGFR). Similarly, clinical evaluations of bariatric surgery patients also depend on eGFR.

Unfortunately, the value of eGFR in bariatric surgery patients using standard estimating equations, the most common clinical method, may be limited. There are several reasons for this. Firstly, the equations were derived from mostly nonobese populations [5–7]. Because serum creatinine is derived from muscle mass, and the muscle mass of severely obese individuals is greater than that of leaner individuals of similar height, this could adversely affect the reliability of the equations [8]. Additionally, weight loss after surgery involves reductions in muscle as well as fat mass [9]. Further complicating this issue is the fact that elevations in glomerular filtration (often called hyperfiltration), which cause a drop in serum creatinine levels, are frequently observed in obese individuals and reversed when weight is lost [10]. Cystatin C, an alternative endogenous marker of glomerular filtration, is arguably not as influenced by muscle mass as is serum creatinine [11], so it may be a more reliable indicator of kidney function in obese individuals. However, it is notable that none of the best validated creatinine- or cystatin-based estimating equations has been carefully evaluated in very obese or bariatric surgery patients.

We therefore assessed the reliability of the most prominent GFR equations and endogenous GFR markers in a cohort of severely obese patients with putatively normal kidney function before and after bariatric surgery by comparing eGFR to mGFR. We hypothesized that cystatin C-based eGFR would better predict mGFR than estimations based on serum cystatin C.

Subjects and Methods

Participants

Study participants were part of several research projects performed between 2004 and 2011 [12, 13, 44] and were recruited from bariatric surgery clinics in the Indianapolis (Ind., USA) area. All subjects except 1 [body mass index (BMI) of 33] were severely obese, defined as a BMI ≥ 35. The relevant institutional review boards approved the protocol (NCT00244790), and all patients gave written informed consent after reviewing a written summary of the plan. The study adhered to the Declaration of Helsinki. A data safety and monitoring board oversaw the study. Inclusion criteria included age 18 or greater, ability to give informed consent and a BMI of 30 or higher. Exclusion criteria included pregnancy, an iodine allergy, a diagnosis of diabetes mellitus, use of an angiotensin-converting enzyme inhibitor or angiotensin receptor block-

Estimating GFR in Bariatric Surgery

...
Results

Participant characteristics before and after surgery are shown in table 1. The 36 study participants were primarily middle-aged, white females who were severely obese by BMI criteria. Nearly all participants had baseline serum creatinine and cystatin C levels that were within the normal range, and many manifested supranormal (hyperfiltrating) levels of mGFR before surgery. Participants were studied an average of 10 months after bariatric surgery, at which time a mean of 37 kg had been lost (p < 0.001), with mean mGFR being 17 ± 6 ml/min lower than presurgery levels (p = 0.007; fig. 1). mGFR was not significantly associated with weight (before: p = 0.12; after: p = 0.20) or BSA (before: p = 0.18; after: p = 0.22) before or after surgery. Change in mGFR was nonsignificantly correlated with change in weight (p = 0.08) but not time after surgery (p = 0.49).

Values represent numbers of patients (percentage) or means ± SD (25th, 75th percentiles), as appropriate. eGFR was converted by means of the following equation: eGFR (ml/min) = eGFR (ml/min/1.73 m²) × BSA (m²)/1.73. CKD-EPI_creat = CKD-EPI equation using serum creatinine only; CKD-EPI_cystC = CKD-EPI equation using serum cystatin C only. CKD-EPI_creat-cystC = CKD-EPI equation using serum creatinine and cystatin C.

Fig. 1. mGFR before and after surgery.
Serum creatinine dropped significantly after surgery (0.1 ± 0.02 mg/dl; p < 0.001), but mean cystatin C did not change (0.03 ± 0.03 mg/l; p = 0.20). Weight before and after surgery was more closely associated with cystatin C (before: r = 0.43, p = 0.009; after: r = 0.49, p = 0.003) than serum creatinine (before: r = 0.40, p = 0.02; after: r = 0.41, p = 0.01), though change in weight was not correlated with either variable. After surgery, mGFR was significantly associated with the inverse of cystatin C (r = 0.38, p = 0.02). However, this relationship did not reach statistical significance in individuals before surgery (r = 0.28, p = 0.09). The inverse of creatinine was not significantly correlated with mGFR either before or after surgery (before: r = 0.26, p = 0.13; after: r = 0.11, p = 0.51; fig. 2).

The overall reliability of GFR-estimating equations is shown in table 2. After expressing both eGFR and mGFR in milliliters per minute, the CKD-EPI creat-cystC was unquestionably the best overall performing estimating equation, showing very little bias and P_{30} of over 80%. Precision and accuracy for the CKD-EPI creat-cystC equation further improved after surgery, with P_{30} increasing to over 83%. After indexing eGFR and mGFR for BSA (i.e. making the units milliliters per minute per 1.73 m^2), bias and accuracy both improved modestly, while precision after surgery fell slightly.

**Discussion**

Identifying a method that best estimates GFR in bariatric surgery patients before and after weight loss has important implications for clinical care of obese patients and research questions related to the impact of obesity and weight reduction on kidney health. In the first study of its kind, we evaluated which of the most validated creatinine- and cystatin C-based GFR-estimating equations best predicts mGFR in a cohort of bariatric surgery patients. We found that the CKD-EPI creat-cystC equation per-
formed the best before and after surgery, regardless of whether or not indexing for BSA was used.

The influence of severe obesity on the assessment of GFR has been insufficiently studied, particularly in light of its relatively high prevalence (nearly 16% of the US adult population has a BMI $\geq 35$) [19] and association with acute and chronic kidney disease [20–23]. While mGFR is the gold standard for assessing kidney function, it involves techniques that are expensive, cumbersome and invasive. In addition, mGFR has its limitations, such as wide variability within individuals and between methods and a lack of benefit over eGFR in predicting outcomes [24]. eGFR has therefore evolved as the standard in the clinical setting. Moreover, even the great majority of research studies examining GFR before and after bariatric surgery use creatinine-based GFR-estimating equations rather than direct measurements [4, 25, 26]. Nevertheless, the use of eGFR in bariatric surgery patients is fraught with potential limitations. Obese persons have proportionally greater muscle mass compared to lean individuals of similar height [8]. This leads to greater creatinine release into the bloodstream and subsequently higher steady-state serum creatinine levels when the GFR is constant. In addition, obesity is frequently associated with glomerular hyperfiltration [27] (as noted in our study population), which results in lower steady-state serum creatin

<sup>a</sup> In milliliters per minute for each left-hand column and milliliters per minute per 1.73 m<sup>2</sup> for each right-hand column.
The result of these multiple and sometimes opposing influences is that the predictive ability of creatinine-based GFR-estimating equations, none of which were derived or validated in very obese populations [5, 7, 15], is unknown, which is why it is so important to validate eGFR in this particular patient subgroup.

Cystatin C is an endogenous glomerular filtration marker that is being studied as an alternative or complement to creatinine. There is reason to believe that serum cystatin C may correlate more closely with GFR than serum creatinine, particularly in subjects with lower creatinine levels [28, 29]. In addition, it is a better predictor of adverse outcomes [30, 31]. Several studies suggest that unlike creatinine, cystatin C is minimally affected by dietary meat consumption [32] or muscle mass [11, 33], although controversy still exists over the latter issue [34, 35]. One particularly compelling report demonstrated that cystatin C levels do not drop after traumatic limb amputations, further suggesting that, unlike with serum creatinine, cystatin C is not influenced by lean mass [36]. The fact that serum cystatin C may be less influenced by body composition than creatinine is not only relevant to estimating GFR in severely obese individuals (who have relatively increased lean mass) but also important to understanding how best to estimate GFR in very obese persons who undergo intentional weight loss because this typically results in loss of both fat and muscle [37]. In our study, serum cystatin C was observed to have a stronger correlation with mGFR than did serum creatinine. In addition, cystatin C also had a statistically significant association with body weight (though weight did not have a similar association with mGFR). These findings suggest that while cystatin C appears to be more closely linked to mGFR and is itself a superior marker of GFR in this population, it is also likely to be influenced by additional factors. Perhaps adipose mass or its secreted inflammatory products account for the observed relationship between weight and cystatin C [38, 39].

An additional issue pertinent to estimating GFR in bariatric surgery patients is the standard of indexing of GFR for BSA in GFR-estimating equations. Adjusting for BSA allows for comparison of GFR between individuals of differing body size, with the underlying assumption being that physiological parameters like GFR are proportional to body size. This is supported by allometric scaling principles in which larger-sized organisms produce a greater metabolic load that leads to a greater filtration capacity [40]. However, as we and others have pointed out [41, 42], applying these concepts to the obese individual is misleading. Obese persons are different than lean subjects in that increases in weight are mostly due to excess adiposity, not lean mass. This difference is important because adipose mass does not significantly contribute to metabolic load [43]. Therefore, adjusting for BSA in obese individuals underestimates the true GFR. Consistent with our concern is the fact that we observed no significant relationship between mGFR and parameters like weight or BSA in this severely obese population. Furthermore, if one is interested specifically in determining the change in GFR after weight reduction within a particular individual, then adjusting for BSA is unnecessary because the number of nephrons does not change as the individual loses weight. While the CKD-EPI\textsubscript{creat-cystC} equation performed similarly with and without indexing for BSA, we believe that indexing should preferably be avoided when studying changes within an individual bariatric surgery patient.

Several prominent, well-validated GFR-estimating equations were evaluated in our study population. Though the CKD-EPI\textsubscript{creat-cystC} equation was less precise than previously reported in leaner populations [5, 7], its bias and accuracy were similar to those of equations used in standard clinical practice (e.g. Modification of Diet in Renal Disease equation, CKD-EPI equation using serum creatinine only) [5]. Interestingly, the combination of serum cystatin C and creatinine greatly improved the predictive value of eGFR over individual creatinine- or cystatin C-based equations. This is surprising, as we expected the cystatin C-based equation to perform better than creatinine-based equations, which it did not. We hypothesize that various influences on creatinine and cystatin C that are unrelated to GFR balanced each other and resulted in improved overall performance.

Our study has several strengths. It is the first study to assess the predictive value of estimating equations before and after bariatric surgery-induced weight loss using a cohort of bariatric surgery patients in whom GFR was directly measured. It therefore provides novel and important information that can be applied to clinical practice and the research setting. It also has some limitations. Our study is of a relatively modest size (though we are unaware of larger studies directly measuring GFR in bariatric surgery patients). The study was performed in patients with normal baseline serum creatinine levels, so caution should be used when applying the findings to patients with existing kidney disease. Body composition measurements were not available for the cohort, which could have helped further define the influence of lean versus fat mass on mGFR. We did not specifically exclude patients who may have had diseases (hypothyroidism) or taken medi-

Estimating GFR in Bariatric Surgery

DOI 10.1159/000357231
cations (glucocorticoids) that could influence cystatin C levels. However, such issues were unlikely to affect our findings in the light of the relatively healthy nature of our study population. We also did not measure dietary protein consumption, which could influence serum creatinine levels though is unlikely to influence mGFR [44].

In conclusion, cystatin C is more strongly associated with mGFR than is serum creatinine in bariatric surgery patients, while the CKD-EPI_creat-cystC equation best predicted mGFR both before and after surgery.
