Cytomegalovirus · Epstein-Barr virus · Human herpesvirus 6 · Community-acquired respiratory viruses · Nasal polyposis · Functional endoscopic sinus surgery

Abstract
Objective: To evaluate the prevalence of human herpesviruses (HHV) 1–6 and community-acquired respiratory viruses (CARVs) in specimens from patients with nasal polyposis undergoing functional endoscopic sinus surgery (FESS) and investigate the potential clinical role.

Methods: Viral occurrence was evaluated by molecular methods in polyp, turbinate mucosa, and pre- and postoperative scraping specimens from 35 consecutive patients at different time points in relation to FESS.

Results: Overall, 21 patients (60%) were positive to at least one virus in at least one specimen; in particular, 12.1% of all specimens for HHV-6 (3/35 polyps, 11/31 turbinates, 1 presurgical scraping) and 10.5% for Epstein-Barr virus (EBV) (8/35 polyps, 3/31 turbinates, 1/29 pre- and 1/29 postsurgical scraping), followed by CMV and HSV-1 (both 1.6%; 1/35 polyps, 1/29 postsurgical scraping and 2/35 polyps, respectively). EBV positivity tended to be higher in polyps, as well as HHV-6 in adjacent healthy turbinate mucosa, although no significant association was found. Only one preoperative cytological specimen was positive to parainfluenza virus-1.

Conclusion: No association between the development of nasal polyps, herpesviruses and CARVs seems to exist. However, the higher EBV frequency in polyps could suggest a causative role or persistence in the inflammatory lymphoid tissue.

Introduction
Nasal polyps are a common chronic disease of nasal and paranasal sinus mucosa, which affects approximately 4% of general population. These benign lesions are characterized by inflammation-induced mucosal swelling, inflammatory cell infiltration, and subepithelial edema. Nasal polyps are usually associated with chronic rhinosinusitis with nasal polyps (CRSwNP) and most common symptoms are obstruction, rhinorrhea, anosmia, facial
pain and headache [1]. Medical therapy consists of intra-
nasal steroids [2] and antibiotics [3]; nevertheless, func-
tional endoscopic sinus surgery (FESS) is often necessary,
despite a 70% chance of recurrence [4]. Pathogenesis and 
molecular mechanisms underlying CRSwNP are poorly 
known; several factors have been investigated, including 
Kirsten rat sarcoma (K-ras) codon 12 mutations/in-
creased expression [5], elevated expression of vascular 
endothelial growth factor A and transforming growth 
factor-β1 [6, 7], as well as clinical features, including al-
lergy, asthma, immunodeficiency and chronic sinus in-
fecions [8, 9]. Viral infections have been hypothesized to 
play a role in the pathogenesis, progression and recur-
rence of CRSwNP [10]. While human papillomavirus has 
been associated rather to neoplastic lesions [11–13], very 
few studies have investigated the role of herpesviruses 
and community-acquired respiratory viruses (CARVs) 
with no definitive conclusions [14]. The Herpesviridae 
family encompasses several DNA viruses that are able to 
establish lifelong latent infections and reactivate in im-
munocompromised conditions; in particular, human 
herpesviruses (HHV) 1–6 (including HSV-1 and -2, VZV, 
Epstein–Barr virus (EBV), CMV) are highly seroprevalent 
and have been associated to upper airway infections.

The aim of this study was to evaluate human herpesvi-
ruses 1–6 and CARVs prevalence by molecular methods 
in nasal polyps, adjacent inferior/middle turbinates, and pre-
and postoperative nasal scraping from patients un-
dergoing FESS.

Materials and Methods

The study population consisted of 35 consecutive patients 
(M/F 25/10; mean age ± SD, 50.3 ± 15.4 years; range 23–77) 
with CRSwNP undergoing FESS between September 2011 and April 
2012 (table 1). All patients gave their informed consent and 
the study was approved by the institutional review board. Diagnosis of 
CRSwNP was made on the basis of European Position Paper on 
Rhin sinusitis and Nasal Polyps (EPOS) 2012 criteria [1]. In detail, 
diagnostic criteria included inflammation of the nose and the pa-
ranasal sinuses characterized by two or more symptoms, one of 
which being either nasal blockage/obstruction/congestion or nasal 
 discharge (anterior/posterior nasal drip); facial pain/pressure; re-
duction/loss of smell for ≥12 weeks; supported by endoscopic 
signs of nasal polyps, mucopurulent discharge, edema/mucosal 
obstruction and/or computed tomography changes. All patients 
were affected by CRSwNP with multiple polyps arising from the 
middle turbinate, middle meatus, or ethmoidal sinuses and were 
classified as grade II–III according to the Mackay and Lund system 
[15]. Pediatric subjects, HIV-seropositive individuals, patients 
with cystic fibrosis, immotile cilia syndrome, allergic fungal rhino-
sinusitis and inverted papilloma were excluded. The following 
time points were considered: T0 (1 month presurgery) clinical his-
tory for allergy and asthma (previous investigation by prick test) 
and preoperative cytological specimen; T1 (surgery) collection of 
two bioptic samples of polyps and the adjacent inferior/middle 
turbinates without polyposis; T2 (1 month postsurgery) postop-
erative cytological specimen (fig. 1). Polymp specimens were col-
lected from maxillary or ethmoid sinus, depending on the involved 
site; scraping for cytological samples was performed on inferior/ 
middle turbinates. Due to missing sending or inadequacy, only 31, 
29, and 29 turbinate pre- and postoperative scraping specimens 
were available, respectively, for an overall number of 124 samples 
for molecular testing.

For processing of mucosa tissues, specimens were incubated 
with 200 μl lysis buffer (Tissue Lysis Buffer; Qiagen, Milan, Italy) 
by brief vortexing and heating at 100°C for 5 min twice, vortexed 
brieﬂy again, then centrifuged for 1 min at 13,000 rpm at room 
temperature. Subsequently, a mechanical lysis step with the roto-
stor homogenizer Tissue Ruptor was performed. A 200-μl ali-
quot of supernatant, as well as of nasal scraping, was subjected to 
real-time PCR was performed, using commercially available kits (Q-PCR 
Complete Kit; ELITech Group, Milan, Italy) following the manu-
facturer’s instructions, and the 7500 Real-Time PCR System (Ap-
plied Biosystems, Monza, Italy). Target regions were glycoprotein 
D and G for HSV-1 and HSV-2, respectively, ORF 29 for VZV, 
EBNA 1 for EBV, exon 4 and UL 123 for CMV, and ORF 13R for 
HHV-6.

The occurrence of CARVs was investigated using a commer-
cially available multiplex PCR assay according to the manufactur-
er’s instructions (RV15 OneStep ACE Detection, Seeplex®; 
Seegene, Seoul, Korea), targeting sequences of influenza A and B 
viruses, RSV type A and B, adenovirus, metapneumovirus, coro-
viruses 229E/NL63 and OC43, parainfluenza viruses 1–4, rhino-
viruses A/B/C, enteroviruses, and bocaviruses 1/2/3/4 and the 
MultiNA System (Shimadzu Corp. Italia, Milan, Italy).

For statistical analysis, χ² and Fisher’s exact tests were applied, as appropriate. A p value <0.05 was considered statistically significant.

Results

The results are summarized in Table 2. Overall, 21 patients (60%) were positive to at least one virus in at least one specimen. As regards herpesviruses 1–6, the highest prevalence was found for HHV-6 (15/124; 12.1%; mean viral load 1,620 ± 1,837 copies/10⁴ cells; median 820) and EBV (13/124; 10.5%; mean viral load 88 ± 140; median 25), followed by CMV and HSV-1 (both 2/124; 1.6%). No specimen was positive to HSV-2 and VZV. In Table 2, prevalence and viral load in different sites for each virus are reported. Viral load was ≤3 × 10³ copies/10⁴ cells in all the cases, except for HHV-6 on a polyp specimen (see below). Considering the type of specimen, EBV was found in 8, 3, and 2 polyp turbinate and cytological (one T₀ and one T₂) specimens, respectively. In 1 patient, EBV was positive in both polyp and turbinate specimens; in another individual, in polyp, turbinate and postoperative cytological samples. In both cases, the highest viral load was found in polyp specimens. HHV-6 was positive in 3 polyps, 11 turbinates, and one T₀ scraping specimen. In 2 patients, both polyp and turbinate specimens were positive to HHV-6, with the highest viral load being detected in the polyp sample (49,000 copies/10⁴ cells). HSV-1 was found in 2 polyp samples, 1 also positive to EBV. CMV was found in 1 polyp (also EBV-positive) and in a T₂ scraping (other samples from the same patient were negative to herpesviruses 1–6). Although EBV positivity tended to be

Fig. 1. Synopsis of specimen collection in study population.

---

Herpesviruses and CARV in Nasal Polyposis
higher in polyps in comparison to other specimens, as well as HHV-6 in turbinate mucosa in comparison to other samples, no statistically significant association was found. Similarly, no significant association between EBV and HHV-6 positivity on polyps and turbinate mucosa, respectively, and clinical features of allergy and asthma was found. As regards CARVs, only one preoperative cytological specimen was positive to parainfluenza virus-1.

**Discussion**

In this study, the prevalence of herpesviruses 1–6 and CARVs in polyp, turbinate mucosa and nasal cytological specimens from patients undergoing FESS for CRSwNP was investigated.

Considering herpesviruses, the highest prevalence was found for HHV-6 (12.1%, irrespective of the type of specimen), followed by EBV (10.5%). CMV and HSV-1 prevalence was very low, while no specimen resulted positive for other herpesviruses. These results are different from those reported in previous studies. As regards EBV, old studies reported EBV-DNA qualitative detection by PCR in 80% of normal nasopharyngeal mucosa from Chinese subjects [16, 17]. In another study on 13 nasal polyps, the same authors found EBV prevalence of 15, 69, and 85% using Southern blot hybridization, qualitative PCR, and in situ hybridization, respectively [18]; this study evidenced a highly different sensitivity with these different methods and led the author to hypothesize that nasal mucosa is a site where EBV persists through a low replicative level in resident lymphocytes. More recently, a 35% EBV positivity in 23 nasal polyps was found by qualitative PCR [19]; whereas in a study on nasal polyps and hypertrophied turbinates from Hong Kong patients, no specimen was positive to EBV in situ hybridization [20]. Taking into account also the different methods and particularly the absence of quantitative molecular data in previous studies, it could be argued that EBV positivity in polyps represents its presence in the inflammatory lymphoid tissue. This hypothesis could be further supported by the fact that EBV was detected at a lower rate in healthy tissue (turbinate mucosa) than in polyps, although the difference was not significant, and by the fact that viral load was always within an order of magnitude of 10^2 copies/10^4 cells. Although EBV can persist in that lymphocytes can be infected by virus released from a lytic EBV infection in the nasal mucosa, the fact that EBV is detected in a high rate in normal nasopharyngeal mucosa tissue (up to 88% in some studies [18]), whereas nasal polyps are much rarer, argues against an EBV contribution to polyp development. This is further supported by data on viral load of the present study and the low number of EBV+ cells in each positive case described by Tao et al. [18].

Only one study investigated HHV-6 prevalence in polyps and inferior turbinates without finding any positive specimen [19]. This is in contrast to the present study in which HHV-6 was detected in >35% of turbinate mucosa specimens and >8% of nasal polyps. This difference could be due to the different methods: quantitative real-time PCR with high specificity and sensitivity in the present study, traditional PCR with 70 bp amplicon length in the study by Zaravinos et al. [19]. The relatively high HHV-6 prevalence in healthy tissues found in our study could be due to its frequent occurrence and diffusion in different tissues. HHV-6 seroprevalence is the highest amongst herpesviruses; furthermore, HHV-6 is the only herpesvirus which is able to integrate its DNA in the human genome, as it can be detectable in chromosomically integrated status in 0.2–0.8% of the general population. Persistence of HHV-6 involves both a true latent state and a low-level chronic replication, each occurring at different anatomic sites, including nasal mucosa. It is to note that a possible limitation of this study is the lack of healthy controls, as well as of normal sinonasal specimens from patients with other underlying pathologies.

Furthermore, we evaluated the presence of CARVs using a multiplex PCR and found only one cytological sample positive to parainfluenza virus-1. These results are in accordance with a previous study on 13 sinonasal mucosa specimens from CRSwNP patients and 2 from healthy subjects that resulted negative to a panel of 12 CARVs [21]. Other authors evaluated the presence of picornaviruses in nasal washing and turbinate mucosa from 39 patients affected by CRSwNP and 27 healthy people and found a 21% rhinovirus positivity in patients, while no virus was found in controls [22]. A more recent study investigated CARVs in paranasal sinus mucosa and polyps by multiplex PCR and found a 18% positivity to bocavirus and <2% positivity to rhinovirus in 102 tissue samples from 88 patients [23]. In the present study, the lack of CARVs detection in any specimen (but the cytological sample) seems to argue against a potential involvement of these viruses in this clinical context.

In conclusion, only EBV and HHV-6 were detected at certain frequency in nasal polyps and adjacent turbinate
mucosa specimens, respectively, although with no statistical significance. To date, the data obtained by the present and other studies seem to argue against a definite role for herpesviruses and CARVs in the development of nasal polyps. Future studies should take into account the relatively higher frequency of EBV detection in polyps that could suggest a causative role in the formation of nasal polyps, as previously suggested by others, or EBV persistence in the inflammatory lymphoid tissue which characterizes these lesions.
