Abstract

Background: Decreased intestinal perfusion may contribute to the development of necrotizing enterocolitis (NEC). Vascular endothelial growth factor (VEGF) is an angiogenic protein necessary for the development and maintenance of capillary networks. Whether VEGF is dysregulated in NEC remains unknown. Objectives: The objective of this study was to determine whether intestinal VEGF expression is altered in a neonatal mouse model of NEC and in human NEC patients. Methods: We first assessed changes of intestinal VEGF mRNA and protein in a neonatal mouse NEC model before significant injury occurs. We then examined whether exposure to formula feeding, bacterial inoculation, cold stress and/or intermittent hypoxia affected intestinal VEGF expression. Last, we visualized VEGF protein in intestinal tissues of murine and human NEC and control cases by immunohistochemistry. Results: Intestinal VEGF protein and mRNA were significantly decreased in pups exposed to the NEC protocol compared to controls. Hypoxia, cold stress and commensal bacteria, when administered together, significantly down-regulated intestinal VEGF expression, while they had no significant effect when given alone. VEGF was localized to a few single intestinal epithelial cells and some cells of the lamina propria and myenteric plexus. VEGF staining was decreased in murine and human NEC intestines when compared to control tissues. Conclusion: Intestinal VEGF protein is reduced in human and experimental NEC. Decreased VEGF production might contribute to NEC pathogenesis.

Introduction

Despite improvements in the survival of premature infants over the last several decades, advances in the treatment of necrotizing enterocolitis (NEC) have not been realized [1]. Indeed, the pathogenesis of NEC is incompletely understood and may be mediated by insufficient blood supply to the intestinal tissue [2].

Vascular endothelial growth factor (VEGF) A controls microvascular development through potent angiogenic, mitogenic and vascular permeability-enhancing activities [3] and may play an important role in the neonatal intestine. Human and mouse milk, which are known to protect against NEC, contain VEGF [4, 5]. Low-birth-weight in-
Infants with polymorphisms associated with decreased VEGF production are more susceptible to NEC [6]. Finally, infants of mothers with preeclampsia, who are at increased risk for NEC [7], have impaired VEGF signaling and decreased fetal free VEGF [8]. Intestinal blood flow has been shown to be impaired in experimental models of NEC [9, 10]. However, the role of VEGF in the development of NEC remains unclear.

We hypothesized that intestinal VEGF is downregulated in the intestine of premature infants at risk for NEC and that decreased VEGF production may contribute to the pathogenesis of the disease. In this study, using a neonatal mouse model established in our lab, we determined whether intestinal VEGF gene and protein expression is altered in pups exposed to the NEC protocol before significant injury occurs [11]. We further examined the effect of isolated NEC protocol stressors on intestinal VEGF gene expression. To correlate our findings to human NEC, we examined mucosal VEGF in murine and human NEC tissues and compared it to controls.

Methods

Human Small Intestinal Tissue Collection

Small intestinal surgical specimens of NEC patients (n = 7) and controls (n = 6; ileal atresia, intestinal reanastomosis, duplication cyst or isolated perforation), all infants under 4 months of age (online suppl. table 1, see www.karger.com/doi/10.1159/000368879), were fixed in 10% formalin and paraffin embedded. Four-micrometer sections were obtained and immunostained for VEGF. Tissue collection was approved by the Lurie Children’s Hospital of Chicago Institutional Review Board.

Neonatal Mouse Model of NEC

Animal studies were approved by the Stanley Manne Children’s Research Institute Institutional Animal Care and Use Committee. Neonatal pups were separated from C57BL/6 dams within 12 h of birth and submitted to our NEC protocol as previously described [12]. The protocol consisted of orogastric inoculation with 107 colony-forming units of standardized adult mouse commensal bacteria (fecal content), exposure to brief episodes of hyperoxia (100% O2, 2 h), which is known to downregulate VEGF in the lung [13], prior to euthanasia and intestinal tissue collection.

To examine the role of antenatal inflammation, given the association between chorioamnionitis and NEC [14], intestines from DF pups of pregnant mice injected with either 100 μg/kg of lipopolysaccharide (LPS) or normal saline intraperitoneally on day 17 of pregnancy were collected on day 1.

Immunohistochemistry

To localize VEGF in mouse and human intestinal tissues, immunohistochemistry on formalin-fixed paraﬁn-embedded slides was performed using rabbit anti-VEGF monoclonal antibody (Abcam, Cambridge, Mass., USA). In mouse tissues, VEGF-positive cells were quantiﬁed in three randomly chosen 40× ﬁelds to generate an average per sample (n = 5 samples per group). In human tissues, VEGF-positive cells and total number of cells in the lamina propria (LP) and epithelial layer were quantiﬁed in three randomly selected average-length villi within three randomly selected 40× ﬁelds by investigators (S.X.L.L. and X.Y.) blinded to the groups. The percentages of VEGF-positive cells were calculated.

Western Blot

To measure intestinal VEGF protein, whole neonatal mouse intestines were homogenized on ice and tissue lysates processed for Western blot analysis with anti-VEGF antibody (SC Biotechnology, Santa Cruz, Calif., USA) using a previously described protocol [15]. Results were expressed as VEGF/β-actin band density ratio.

Real-Time RT-PCR

To measure intestinal VEGF mRNA, neonatal mouse intestines were preserved in RNALater (Qiagen, Valencia, Calif., USA). After tissue homogenization over ice, total RNA was puriﬁed using a Qiagen RNeasy Kit, and real-time RT-PCR was performed as previously described [15] using the following primers: VEGF164 (VEGF-A) forward, 5′-GCA GCC TGC TGT AAC GAT GA-3′; VEGF reverse, 5′-GCA TGA TCT GCA TGG TGA TGT T-3′; GAPDH forward, 5′-CTT CAC CAC CAT GGA GAA GCC-3′; GAPDH reverse, 5′-GGC ATG GAC TGT GGT CAT GAG-3′. VEGF gene expression was normalized to GAPDH (ΔCT = GAPDH – VEGF) as internal control. All samples were run in duplicate. Nontemplate controls were run in parallel and their ﬂuorescence did not cross the threshold. There was a single product on melting curve analysis for VEGF and GAPDH.

Statistical Analysis

Two-sided Student t test was performed for the comparison of two groups, and one-way analysis of variance (ANOVA) for multiple-group comparisons. For immunohistochemistry and Western blot analysis, data were expressed as the mean ± standard error of the mean (SEM) and, for RT-PCR, as mean difference with conﬁdence intervals (CI). Results were considered statistically signiﬁcant when p value <0.05.
Results

**Intestinal VEGF Protein Is Decreased in a Neonatal Mouse NEC Model**

To test the hypothesis that VEGF is decreased in NEC, neonatal mouse pups were exposed to our NEC protocol [12]. When examined by Western blot, intestinal VEGF was decreased in pups submitted to the NEC protocol for 24 h (NEC/DF = 0.08 ± 0.03 fold; DF, n = 15; NEC, n = 6; p < 0.001) and 48 h (NEC/DF = 0.10 ± 0.04 fold; n = 4 per group; p < 0.05) when compared to their age-matched DF controls (fig. 1a, b).

To remove breast milk, which is known to contain VEGF [4], intestinal lumens were washed prior to protein extraction and Western blot analysis. In washed intestines, we observed a similar reduction in intestinal VEGF in stressed pups compared to DF controls (NEC/DF = 0.02 ± 0.01 fold; DF, n = 3; NEC, n = 4; p < 0.001; fig. 1c). To further confirm that this difference in intestinal VEGF reflects VEGF tissue changes, VEGF was localized by immunohistochemistry (fig. 2).

**Intestinal VEGF mRNA Is Decreased in Experimental NEC**

To examine whether the decrease in intestinal VEGF protein is due to a decrease in VEGF gene expression, we assessed intestinal VEGF mRNA by real-time RT-PCR. At 24 h, when intestinal injury is rarely detected [11], we found that intestinal VEGF mRNA expression was significantly downregulated in stressed pups compared to controls (mean difference: 0.31, CI 0.01–0.6; p < 0.001; fig. 3a), suggesting that the differences in intestinal VEGF protein result at least in part from a decrease in gene expression. VEGF expression remained low at 48 and 72 h (results not shown). When pups exposed to the NEC protocol for 24 h were returned to dams to be DF for another 24 h, VEGF expression recovered to levels similar to controls (mean difference compared to pups stressed for 48 h: −0.5, CI −0.9 to −0.2; p < 0.01; fig. 3b).

**Intestinal VEGF Is Decreased in Association with Experimental Stressors That Cause NEC**

To determine which neonatal stressors affect VEGF expression in our experimental NEC model, DF pups were exposed to cold stress, hypoxia or adult commensal bacteria, alone or in combination, or to hyperoxia alone as a positive control. Another group was formula fed only. We found that exposure to either formula feeding (mean difference: 0.05, CI −0.3 to 0.4; not significant), cold stress (mean difference: 0.16, CI −0.2 to 0.6; not significant), hypoxia (mean difference: 0.04, CI −0.4 to 0.4; not significant), or adult commensal bacteria alone (mean difference: 0.16, CI −0.3 to 0.6; not significant) was not significantly associated with changes in VEGF expression (fig. 4a). VEGF was significantly downregulated when DF mice were exposed to bacteria inoculation, cold stress and hypoxia together (mean difference: 0.54, CI 0.13–0.9; p < 0.01), and when exposed to hyperoxia alone (mean difference: 0.53, CI 0.13–0.94; p < 0.01; fig. 4a). Antenatal maternal LPS injection caused a decrease in intestinal VEGF expression in the pups compared to controls (mean difference: 0.32, CI 0.19–0.45; p < 0.001; fig. 4b).
Small Intestinal VEGF Staining Is Decreased in Experimental NEC and in Human NEC Patients

When murine intestinal tissues were immunostained with a monoclonal antibody against VEGF, we found a significant reduction in VEGF-positive cells in the small intestinal LP of mice exposed to our NEC protocol for 24 h compared to DF controls (n = 5 per group; DF 82.8 ± 6.6; NEC 48.8 ± 1.9; p < 0.005; fig. 5). No significant injury is typically detected by 24 h in our model [11]. In intestinal tissues obtained from human subjects (online

Fig. 2. VEGF localizes to cells of the intestinal epithelium, the lamina propria and the myenteric plexus in the neonatal mouse small intestine. The small intestines of day-1 DF pups were immunostained for VEGF. a Positive staining shown in mesenteric vessels as well as in the LP, myenteric plexus and few single cells of the epithelium. b The specificity of VEGF staining was confirmed by positive staining of mouse placental vascular cells (c, positive control) and by the absence of staining in intestinal tissues when the primary antibody was omitted (b, negative control). LP = Lamina propria; Ep = epithelium; MP = myenteric plexus; MV = mesenteric vessels.

Fig. 3. Intestinal VEGF mRNA expression is downregulated in a neonatal mouse model of NEC. a Pups exposed to the NEC protocol for 24 h (n = 9) and DF controls (n = 7) were sacrificed and their intestines collected. VEGF mRNA expression was measured by real-time RT-PCR, normalized to GAPDH and expressed as fold-expression relative to DF controls. b Pups exposed to the NEC protocol for 24 h were returned to the dams for 24 h prior to intestine collection. * p < 0.01; ** p < 0.001.

Color version available online
suppl. table 1), we found a lower percentage of VEGF-positive cells in NEC patients (n = 7) when compared to control samples (n = 6) overall, as well as fewer VEGF-positive cells in the LP and epithelial cell layers specifically (overall percentage of VEGF-positive cells: control 21 ± 1; NEC 10 ± 1; p < 0.0001; percentage of VEGF-positive LP cells: control 52 ± 3; NEC 23 ± 1; p = 0.0001; percentage of VEGF-positive epithelial cells: control 36 ± 2; NEC 17 ± 2; p < 0.0001; fig. 6). Healthy areas beyond the necrotic zones were selected for VEGF quantification in order to avoid the possibility that VEGF protein detection would be hampered by intestinal tissue degradation.

Discussion

The intestinal circulation has long been suspected to contribute to the pathogenesis of NEC [9, 16]. Evidence that alterations in intestinal microvascular blood flow may play a role in NEC has been found in both animals [9, 10] and human subjects [17]. Although VEGF signaling is impaired in several diseases that uniquely affect neonates, as well as in animal models of those conditions [18–20], whether VEGF expression is altered in the intestine in NEC remains unknown. A pilot study showed that VEGF protein is decreased in a neonatal mouse NEC model [unpublished data: Carrasco et al: Federation of American Societies for Experimental Biology, Anaheim, CA, 2010. Abstract No. 1007.3], and this finding was confirmed in neonatal rats exposed for 3 days to formula feeding, 100% CO2, cold stress and hyperoxia [21]. In this study, we further examined the role of perinatal stressors in NEC and how VEGF is affected in human NEC.

Here, we show that VEGF protein is decreased in small intestine specimens resected from premature neonates with NEC. To determine whether the decrease in VEGF expression occurs prior to intestinal injury, pups were submitted to our NEC protocol for 24 h, before intestinal injury is commonly seen, and compared to DF controls [11]. We found that VEGF protein assessed by Western blot was strongly decreased in stressed pups, due at least in part to downregulation of VEGF gene expression. Furthermore, we found that while exposure to stressors individually did not significantly change intestinal VEGF

**Fig. 4.** Commensal bacteria, cold stress and hypoxia administered together, and exposure to antenatal inflammation alone, down-regulate VEGF mRNA expression in the intestine of neonatal mice. **a** DF or formula-fed pups were submitted for 24 h to cold stress, hypoxia or commensal bacteria exposure alone or in combinations. DF mice submitted to hyperoxia alone for 2 h were used as positive control. VEGF mRNA expression was measured by real-time RT-PCR, normalized to GAPDH and expressed as fold-expression relative to age-matched DF controls (*p < 0.05; †p < 0.01). **b** Intestinal VEGF expression was reduced in 24-hour DF pups exposed to antenatal inflammation by prenatal LPS treatment of the dam compared to controls (p < 0.001). FF = Formula fed; B/H = bacteria and hypoxia; B/C/H = bacteria, cold stress and hypoxia.
Fig. 5. VEGF staining is decreased in intestinal tissues of mice submitted to a NEC protocol. After immunostaining tissues for VEGF, we found significantly fewer VEGF-positive cells in the small intestinal LP of mice exposed to our NEC protocol (b, enlarged in d) compared to DF controls (a, enlarged in c). Quantification of VEGF + cell per field (×20 magnification). e * p < 0.005.

Fig. 6. VEGF staining is decreased in small intestinal tissues of human NEC patients. Immunohistochemical staining was performed on human small intestinal samples using VEGF antibody. Control cases (a, enlarged in c) showed VEGF-positive cells in the intestinal epithelial cell layer and the LP. We found significantly fewer VEGF-positive cells in small intestinal tissue samples resected from NEC patients (b, enlarged in d) compared to control samples (a). e * p < 0.005; ** p < 0.0001. VEGF positive cell percentage in LP, EC and total cells of the villi. f The intestinal wall of a control case is shown here with enlarged areas (g, h) showing VEGF staining in mesenteric vessels and myenteric plexus. EC = Epithelial cell layer; MV = mesenteric vessels; MP = myenteric plexus.
gene expression, bacterial inoculation, hypoxia and cold stress together significantly downregulated intestinal VEGF expression. Hyperoxia alone also downregulated intestinal VEGF expression, which is consistent with findings in other tissues [22]. Antenatal inflammation has been shown to be an independent risk factor for NEC [14]. Interestingly, we found that antenatal maternal exposure to LPS decreased VEGF expression in the intestine of 1-day-old mice. A limitation of our study is the absence of correlation between VEGF expression and NEC severity in either experimental or human samples.

The few studies that have localized VEGF in intestinal tissues have reported inconsistent findings across studies and species [23–26]. Ubiquitous VEGF staining has been noted in fetal sheep small intestines [23] and in human adult tissues affected by inflammatory bowel disease [25, 26]. Conversely, a study of human neonatal small intestines has reported VEGF expression solely in endothelial cells [24]. These inconsistencies may result from the variable affinity and lack of specificity of the most commonly used VEGF primary antibodies [27]. In this study, using a monoclonal antibody, we have localized VEGF to specific cells in both human and mouse neonatal intestinal tissues, and we have shown that mucusal VEGF staining is decreased in both murine and human NEC.

In conclusion, we have shown that in the intestine of newborn mice exposed to a NEC protocol, intestinal VEGF mRNA and protein are decreased before significant histologic injury occurs. VEGF is present in both human and mouse neonatal intestinal tissues, and VEGF is decreased in the intestinal mucosa of mice exposed to a NEC protocol and human infants with surgical NEC. These findings suggest that VEGF downregulation may play a role in NEC. Additional studies aimed at modulating VEGF expression in our NEC model are needed to further elucidate the role of VEGF in NEC.
