Abstract

Background/Aims: Numerous epidemiological studies have associated elevated serum phosphorus levels with cardiovascular disease and the risk of death in the general population as well as in chronic kidney disease (CKD) and dialysis patients. In this study, we explored whether elevated phosphate conditions induce cardiac hypertrophy and attempted to identify the molecular and cellular mechanisms in the hypertrophic response. **Methods:** H9c2 myocardial cells were incubated in high-phosphate conditions to induce hypertrophy. Pathological hypertrophic responses were measured in terms of cell size, arrangement of actin filaments, and hypertrophy markers such as atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP) in myocardial cells. Several transcriptional factors involved in cardiac hypertrophy development were measured to investigate the molecular pathways involved in elevated phosphate-induced cardiac hypertrophy. **Results:** High-phosphate conditions induced cellular hypertrophy, marked by increased cell size, reorganization of actin filaments, and upregulation of both ANP and BNP in H9c2 cells. Both upstream calcineurin and downstream transcription factors, including GATA-4 and NFAT-3, were significantly increased under hyperphosphate conditions. Moreover, both MEK1/2 and ERK1/2 expression increased significantly, and cellular hypertrophy was markedly attenuated by U0126, an ERK1/2 inhibitor. **Conclusions:** These results suggest that hyperphosphate conditions induce myocardial hypertrophy through the ERK signaling pathway in H9c2 cells. Our findings provide a link be-

tween the hyperphosphate-induced response and the ERK/NFAT-3 signaling pathway that mediates the development of cardiac hypertrophy. In view of the potent and selective activity of the ERK inhibitor U0126, this agent warrants further investigation as a candidate for preventing hyperphosphate-induced cardiac hypertrophy in CKD and dialysis patients.

Introduction

Phosphate levels are strongly associated with poor outcomes in patients with chronic kidney disease (CKD) and end-stage renal disease (ESRD) [1–4]. Several epidemiological studies have documented a link between serum phosphorus and adverse outcomes in CKD [3, 4]. In addition, a high serum phosphate level is also highly correlated with the extent of vascular calcification and vascular disease [5]. Many people worldwide have combined cardiovascular disease and CKD [6]. Cardiovascular complications are the major cause of death in patients with ESRD [7]. More recent observational data have associated hyperphosphatemia with increased cardiovascular mortality among dialysis patients [8, 9]. Phosphorus levels are also associated with subclinical atherosclerosis in the general population and young adults [10, 11]. A recent report has demonstrated that conventional hemodialysis is associated with significant left ventricular hypertrophy [12]. Abnormal mineral metabolism, especially hyperphosphatemia, is now considered a novel cardiovascular risk factor among dialysis patients. However, the reasons and mechanisms responsible for phosphorus dampening are only partially understood, because the putative receptor mediating phosphorus toxicity in target organs has not yet been identified.

Intracellular signaling pathways of the cardiac hypertrophic response are typically induced by active membrane-bound receptors including multiple GTPase proteins, kinases, and phosphatases [13]. In the heart, mitogen-activated protein kinase (MAPK) signaling pathways and the Ca^{2+} /calmodulin-activated protein phosphatase calcineurin have been reported to participate in the development of cardiac hypertrophy in response to stimuli [13–15]. However, no experiments have been conducted to establish a causal relationship between hyperphosphate and hypertrophy of myocardial cells. In the present study, we first examined whether hyperphosphate induces cardiac hypertrophy and subsequently identified the precise molecular and cellular mechanisms involved in the hypertrophic response induced by hyperphosphate in myocardial cells.

Materials and Methods

Elevated Phosphate-Induced Hypertrophy in Myocardial Cells

Cardiomyoblast cells (H9c2) were cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum (Clontech, Mountain View, Calif., USA), 2 mM glutamine, 1 mM HEPES buffer, and antibiotics (100 µg/ml penicillin, 100 µg/ml streptomycin) in 5% CO_2 at 37°C. For treatment with elevated phosphate, the H9c2 cells were incubated in different concentrations of NaH_2PO_4 . Cell sizes were calculated at various time intervals. Finally, the best condition was used to induce cellular hypertrophy in myocardial cells.

Cell Size Measurement

The cell surface area was determined after imaging by fluorescence microscopy. H9c2 cells were fixed with 4% paraformaldehyde, washed with ice-cold PBS, permeabilized with 0.5% Triton X-100, and blocked with PBS containing 2% bovine serum albumin as described previously [16]. Actin filaments were stained using rhodamine-labeled phalloidin (Molecular Probes, USA). Surface areas were quantified by visualizing the boundary of individual cells by using Zeiss AxioVision software. For each treatment condition, 30 cells were counted in triplicate.

Immunoblotting

Crude proteins of cultured myocardial cells were isolated using lysis buffer (Roche Molecular Biochemicals, Indianapolis, Ind., USA). Nuclear protein was extracted as per a protocol reported previously [16]. The protein concentration in the supernatant was determined by the colorimetric assay (Bio-Rad, Hercules, Calif., USA). Samples containing 50 µg of protein were analyzed by Western blot. Antibodies against atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), GATA-4, phosphorylated GATA-4, and NFAT-3, as well as goat anti-mouse IgG antibody conjugated to horseradish peroxidase, goat anti-rabbit IgG antibody conjugated to horseradish peroxidase, and goat anti-rabbit IgG horseradish peroxidase conjugate were obtained from Santa Cruz Biotechnology Inc. (Santa Cruz, Calif., USA). We used α-tubulin (Lab Vision Corporation, Fremont, Calif., USA) as the loading control.

Inhibitor Treatments

p38 MAPK inhibitor (SB203580), JNK inhibitor (SP600125), ERK1/2 inhibitor (U0126), and calcineurin inhibitor [cyclosporine A (CsA)] were obtained from Tocris (Ellisville, Mo., USA). H9c2 cells were preincubated with U0126 (1 µM), SB203580 (1 µM), SP600125 (1 µM), and CsA (1 µM) for 1 h, followed by NaH₂PO₄ for 6 h. Actin immunofluorescence was performed to determine the effect of these inhibitors on the cardiomyocyte hypertrophy induced by elevated phosphate conditions.

Statistical Analysis

All statistical analyses were conducted using SPSS 13.0 software. Each experiment was replicated at least 3 times. The results are presented as the average mean ± standard error (SE), and statistical comparisons were made using Student's t test. A p value <0.05 was considered statistically significant.

Results

Hyperphosphate Conditions Induce Cellular Hypertrophy and Upregulate the Pathologic Hypertrophy Markers ANP and BNP in Myocardial Cells

Myocardial cells showing hypertrophy induced by elevated levels of phosphate were analyzed by performing immunofluorescence to examine actin fibers and cell sizes. The results showed that the surface area of H9c2 cells increased significantly, approximately 1.3-, 1.8-, 1.5-, and 1.2-fold in response to 1.2, 1.4, 1.6, and 1.8 mM NaH₂PO₄ treatment, respectively, as compared to the control. In addition, the H9c2 cell surface area increased significantly at different time intervals under 1.4 mM NaH₂PO₄ treatment conditions (fig. 1).

Cell lysates were analyzed for the pathologic hypertrophy markers ANP and BNP. As shown in figure 2, H9c2 cell cultures were treated with 1.4 mM NaH₂PO₄ for 24 h and analyzed by Western blot using antibodies against ANP and BNP. ANP significantly increased within 1 h following treatment, and the levels were maintained for up to 24 h. BNP levels increased 6 h after treatment and reached a maximum at 24 h.

Elevated Phosphate Conditions Induce an Increase in Calcineurin Expression, GATA-4 Activation, and NFAT-3 Nuclear Localization in Myocardial Cells

As shown in figure 3, elevated phosphate conditions induced an increase in calcineurin expression within 6 h and phosphorylation/activation of GATA-4 within 3 h, and the active state of GATA-4 was maintained for up to 24 h. NFAT-3 levels increased in a time-dependent manner during the first 12 h. These results suggest that elevated phosphate conditions induce the development of myocardial hypertrophy through calcineurin and the activation of GATA-4 and nuclear localization of NFAT-3.

MAPKs Mediate Elevated Phosphate-Induced Myocardial Hypertrophy

To further elucidate the signal transduction pathway involved in the mechanism of elevated phosphate-induced myocardial hypertrophy, MAPKs such as ERK, MEK, JNK, and

Fig. 1. Cell size measurements in elevated phosphate-induced hypertrophic myocardial cells, performed using actin immunofluorescence staining. H9c2 myocardial cells were cultured with different concentrations of NaH_2PO_4 and treated with 1.4 mM NaH_2PO_4 for various time periods (1, 2, 6, 12, and 24 h). The cell surface area was observed using fluorescence microscopy. The results are expressed as the mean $\pm$ SE values of 3 experiments. * $p < 0.05$, ** $p < 0.01$ in comparison to the control.

p38 were analyzed by Western blot. Elevated phosphate-induced myocardial hypertrophy increased the expression of ERK only at 6 h after treatment. In addition, the level of MEK expression increased within 1 h and decreased after 6 h as compared to the control (fig. 4). These results show that the MAPK pathway is involved in elevated phosphate-induced myocardial hypertrophy.

Potential Inhibitors of Elevated Phosphate-Induced Myocardial Hypertrophy

To confirm the involvement of the MAPK signal transduction pathway and identify potential inhibitors of elevated phosphate-induced myocardial hypertrophy, the signal transduction inhibitors CsA (calcineurin inhibitor), U0126 (ERK1/2 inhibitor), SB203580 (p38 MAPK inhibitor), and SP600125 (JNK1/2 inhibitor) were used to block MAPK and calcineurin-mediated pathways in H9c2 cells. The results showed that the ERK1/2 inhibitor U0126 suppressed elevated phosphate-induced cell size hypertrophy significantly (fig. 5). CsA and the other MAPK inhibitors, namely SB203580 and SP600125, had no effect on cell size in phosphate-induced hypertrophy (fig. 5). These results indicate that the Ca^{2+} /calmod-

ulin-activated protein phosphatase calcineurin is not involved in the regulation of elevated phosphate-induced hypertrophy. They confirm that ERK1/2 play an important role in elevated phosphate-induced myocardial hypertrophic response.

Discussion

High serum phosphate is a major risk factor for cardiovascular disease and vascular calcification. Numerous epidemiological studies have associated serum phosphorus levels with different markers of cardiovascular disease [2, 5, 10, 11] and the risk of death in the general population [6, 17] as well as in CKD and dialysis patients [1, 3, 4]. Therefore, establishing a causal relationship between elevated serum phosphate levels and hypertrophy of myocardial cells is essential. In this study, we first explored the molecular and cellular mechanisms behind the hypertrophic response induced by elevated phosphate conditions in myocardial cells. We demonstrated that elevated phosphate conditions induce a hypertrophic response in H9c2 cells, marked by an increased cell surface area, a reorganization of actin filaments, and an upregulation of hypertrophy markers (ANP and BNP). Both transcription factors GATA-4 and NFAT-3 are important for the development of cardiac hypertrophy. Finally, our results demonstrated that the characteristic features of cardiac hypertrophy in H9c2 cells are mediated by the ERK1/2 signaling pathway (fig. 6).

Fig. 3. Expression of calcineurin and GATA-4 and nuclear localization of NFAT-3 in elevated phosphate-induced myocardial cells with 1.4 mM NaH₂PO₄. The protein levels of calcineurin, GATA-4, and phosphorylated (p-)GATA-4 and the nuclear fraction of NFAT-3 were determined by Western blot analysis. The results are expressed as the mean ± SE values of 3 experiments. ** p < 0.01 in comparison to the control. Tub = α-Tubulin.

The MAPK pathway is important in transferring external stimuli to the nucleus via the phosphorylation and regulation of several transcription factors. Serine-threonine kinases have been shown to phosphorylate important downstream mediators that participate in the regulation of cellular functions such as proliferation, differentiation, apoptosis, and growth processes including cardiac hypertrophy [18]. MAPKs can be divided into three subfamilies on the basis of sequence homology, namely ERKs, JNKs, and p38. Growing evidence shows

Fig. 4. Expression of MAPK markers in elevated phosphate-induced myocardial cells with 1.4 mM NaH₂PO₄. The protein levels of MEK1/2, phosphorylated (p-)ERK1/2, p-MEK1/2, p-JNK, and p-p38 were determined by Western blot analysis. The results are expressed as the mean $\pm$ SE values of 3 experiments. * $p < 0.05$, ** $p < 0.01$ in comparison to the control. Tub = α -Tubulin.

that environmental stress (osmotic stress, DNA damage, and ultraviolet radiation) stimulates cardiomyocyte hypertrophy and activates protein kinase cascades including ERK, p38 MAPK, and JNK [19]. Interestingly, the significant role for these pathways in hypertrophic signaling was confirmed by overexpression of MAPK phosphatase 1, which inhibits all three major factors of MAPK signaling and blocks cardiac hypertrophy both in vitro and in vivo [20]. In this study, pretreatment with ERK, but not with JNK or the p38 MAPK inhibitor, showed suppressive effects on hypertrophic changes such as the reorganization of actin filaments. These results indicate that hypertrophy is specifically suppressed by an ERK inhibitor.

A previous study has demonstrated that the calcineurin/NFAT signaling pathway plays an important role in the development of cardiac hypertrophy [21]. It was also shown that calcineurin activity is increased in compensated hypertrophic human myocardium and end-stage heart failure [22]. However, pretreatment with the calcineurin inhibitor CsA showed slight effects on hypertrophic features such as the reorganization of actin filaments in this study. These results suggest that the Ca²⁺/calmodulin-activated protein phosphatase calcineurin is not involved in elevated phosphate-induced hypertrophic responses of H9c2 myocardial cells.

Another previous study has indicated that poor outcomes in patients with CKD and ESRD were associated with serum phosphate levels [23]. Additionally, observational studies have

Fig. 5. Potential inhibitors of elevated phosphate-induced myocardial hypertrophy. H9c2 myocardial cells were pretreated with potential inhibitors, namely CsA (calcineurin inhibitor), U0126 (ERK1/2 inhibitor), SB203580 (p38 MAPK inhibitor), and SP600125 (JNK1/2 inhibitor), for 1 h and subsequently underwent elevated phosphate treatment (1.4 mM) for 6 h. Cells cultured without pretreatment were used as a control. The effect of various inhibitors on elevated phosphate-induced myocardial hypertrophy was determined by the actin immunofluorescence assay. The relative cell size in response to different inhibitors was analyzed, where 30 cells were counted in each experiment, performed in triplicate. The results are expressed as the mean $\pm$ SE values of 3 experiments. ** $p < 0.01$ in comparison to the control; ## $p < 0.01$ in comparison to phosphate treatment.

Fig. 6. Signaling pathway involved in phosphate-induced myocardial hypertrophy. Phosphate-induced myocardial hypertrophy critically prompts the activation of calcineurin. Calcineurin dephosphorylates the NFAT-3 transcription factor in the cytoplasm, and the dephosphorylated NFAT-3 further interacts with the GATA-4 transcription factor in the nucleus to turn on the expression of hypertrophy response genes such as ANP and BNP that participate in the development of myocardial hypertrophy. Administration of the pharmacological agent CsA may completely block calcineurin enzymatic activity but may have no significant inhibitory effect on myocardial hypertrophy. Moreover, MEK1/2-ERK1/2 expression both increase significantly, and cellular hypertrophy is markedly attenuated by U0126, an ERK1/2 inhibitor. These results suggest that hyperphosphate induces myocardial hypertrophy through the ERK signaling pathway in H9c2 cells.

correlated the use of phosphate binders as a tool for controlling hyperphosphatemia with better survival rates in CKD and ESRD [7, 24]. However, the use of phosphate binders in CKD is based on observational rather than clinical trial data, and these suggest only a limited effect of phosphate binders [24]. This study revealed that elevated phosphate levels induce myocardial hypertrophy in H9c2 cells via the ERK signaling pathway. To prevent cardiac hypertrophy in CKD and dialysis patients, we propose that blocking the ERK/NFAT-3 signaling pathway – using a pharmacological ERK inhibitor such as U0126 – may be a good therapeutic approach, thus preventing pathological hypertrophy and heart dysfunction. Considering the growing incidence of dialysis and CKD, we believe that this area should be prioritized for future research. Further studies are required to explore candidate ERK inhibitors for clinical applications.
