Key Words

Dyschromatosis · Dyschromatosis universalis hereditaria · Dyspigmentation · End-stage renal disease · Renal failure

Abstract

Dyschromatosis universalis hereditaria (DUH) is a rare autosomal dominant inherited dermatosis which usually appears during childhood and is characterized by dyspigmentation, with both hypopigmented and hyperpigmented macules. We report a case of DUH with unexplained childhood-onset renal failure. The association between DUH and renal failure is yet to be proven by further studies.

Case Report

A 16-year-old male presented with asymptomatic, slowly progressive abnormality of skin color, beginning when he was 1 year old. The lesions were first noticed on his chest and back, and subsequently involved his entire body except the palms and soles. At the age of 14, he had acute febrile illness followed by asymptomatic gross hematuria. The gross hematuria resolved within a couple of weeks, although it recurred intermittently. His renal function gradually deteriorated, eventually becoming end-stage renal disease. The definitive cause of renal failure could not be determined because of late presentation of the patient. A presumptive diagnosis of IgA nephropathy was made according to the clinical presentation. He currently requires renal dialysis and is awaiting kidney transplantation. He denied photosensitivity and previous exposure to arsenic or herbal medication. The patient and his family also denied a history of skin cancers. Many of his family members have similar skin dyspigmentation, as shown in the family pedigree (fig. 1). The onset of lesions in all involved members

occurred in childhood, as in our patient. There was no family history suggestive of renal disease.

Physical examination revealed generalized symmetrical hypopigmented and hyperpigmented macules, varying from 2 to 5 mm in size, on the face, trunk, extremities and dorsum of both hands and feet, sparing the palms and soles (fig. 2, fig. 3). There was no abnormality of oral mucosa or nails. Abdominal examination was normal. No mass could be palpated by bimanual palpation. Neurological examination was also normal.

Discussion

Dyschromatosis universalis hereditaria (DUH) is a rare inherited dyschromatosis, characterized by the appearance of both hypopigmented and hyperpigmented macules that can involve almost all parts of the body. The disease is usually autosomal dominant inheritance, with a few autosomal recessive and sporadic cases reported. Recently, a mutation in the *ABCB6* gene was identified as the pathologic gene in DUH. However, not all DUH patients have the *ABCB6* mutation. It is possible that DUH is a disease of genetic heterogeneity [1–3].

The main feature of DUH is a mixture of hypopigmented and hyperpigmented macules, distributed symmetrically. The lesions can occur anywhere on the body, but rarely involve the palms and soles. Facial lesions are found in approximately 50% of individuals. The lesions usually appear in infancy or early childhood and stop spreading before adolescence, after which the lesions will last for life [4–6]. The differential diagnoses of DUH are shown in table 1. Except for skin lesions, there is no other common associated condition in DUH; however, there have been various reports of an association with short stature and high-tone deafness, seizure, mental retardation, hair and nail abnormalities, ocular abnormalities and thrombocytopenia [4, 6–8]. Still, most DUH patients do not show any association. Furthermore, there have been no reports of malignant transformation of the lesions in DUH patients.

Histologically, hyperpigmented lesions of DUH contain more melanin than either normal or hypopigmented macules. In both hypopigmented and hyperpigmented lesions, melanocytes are found in normal number. Based on electron microscopic examination, a difference in the amount of fully melanized melanosomes in hypopigmented and hyperpigmented lesions was found. However, there was no difference in melanocyte number and tyrosinase activity. Therefore, DUH is not a disorder of melanocytes, but rather a defect of melanosome synthesis or transport [9, 10].

A definitive treatment has not been established for DUH. In most cases, patient education and reassurance are recommended. Although in a recent report hyperpigmented macules were successfully treated with a Q-switched alexandrite laser, longer follow-up of the result is needed [11]. In the present case, cosmetic appearance is not a concern. However, since the patient is scheduled for kidney transplantation, there is a question of malignant transformation of his skin lesions. In our opinion, the lesions of DUH should not increase the risk of skin cancer for the average transplant patient, and indeed DUH has thus far never been associated with such a risk. However, since the pathogenesis of DUH still remains to be elucidated, we plan to follow up on the patient's condition in the future.

Our patient demonstrates the typical cutaneous presentation and inheritance in his family. His family tree clearly demonstrates an autosomal dominant pattern of the disease. Thus, our case gives further support to the previous evidence that DUH is an autosomal dominant disease. Furthermore renal failure, which occurred in our case, has never been previously reported in the literature. Renal involvement may be another internal organ manifestation in patients with DUH. However, renal biopsy was not performed due to the late presentation of

renal failure in this case. Therefore, whether the occurrence of renal failure is a true association or a coincidence remains inconclusive. Further study is needed to prove this association.

Table 1. Differential diagnoses of DUH

Disease	Inheritance	Morphology	Location	Associations
DUH	AD	mixture of both hyperpigmented and hypopigmented macules	generalized	learning difficulty, deafness, mental retardation, thrombocytopenia ¹
Dyschromatosis symmetrica hereditaria	AD	mixture of both hyperpigmented and hypopigmented macules	face, dorsum of hands and feet	none
Dyschromic amyloidosis	AR	mixture of both hyperpigmented and hypopigmented macules	generalized	none
Xeroderma pigmentosum	AR	freckle-like hyperpigmentation; hypo-/hyperpigmentation, poikiloderma	sun-exposed areas	skin cancers, photophobia, keratitis, deafness, mental retardation
Chronic arsenic toxicity	acquired	guttate hypopigmentation superimposed on hyperpigmentation	any part of the body	skin cancers, internal malignancy

AD = Autosomal dominant; AR = autosomal recessive.

¹ Most of the reported cases had no association, but some reported learning difficulty, deafness, mental retardation or thrombocytopenia [4, 8].
