Abstract

Unilateral carotid cavernous fistula presents with ipsilateral ocular findings. Bilateral presentation is only seen in bilateral fistulas, usually associated with indirect (dural) carotid cavernous fistulas. Direct carotid cavernous fistulas are an abnormal communication between the internal carotid artery and the cavernous sinus. They typically begin with a traumatic disruption in the artery wall into the cavernous sinus, presenting with a classic triad of unilateral pulsatile exophthalmos, cranial bruit and episcleral venous engorgement. We report the case of a 38-year-old male with traumatic right carotid cavernous sinus fistula and bilateral ocular presentation successfully treated by interventional neuroradiology.

Introduction

Carotid cavernous fistulas (CCF) are uncommon disorders characterized by abnormal communications between the internal carotid artery (ICA) and the cavernous sinus (CS) [1, 2]. Barrow et al. [1] divided CCF in four categories, with direct communications between ICA-CS characterizing type A. Types B, C and D are indirect dural shunts, having low blood flow [2]. Direct and indirect fistulas have different pathogenesis, with the last arising from meningeal arteries of the external and/or ICA [2]. Direct connections have a high flow

through the ICA wall and are posttraumatic in 75% of cases [1, 3]. Other etiologies include cavernous ICA aneurysm rupture, arterial dissection, connective tissue disorders, iatrogenic causes and fibromuscular dysplasia [2, 4–6]. The mixing of venous and arterial blood leads to a venous hypertension transmitted to the orbital content. The classic clinical triad is pulsatile exophthalmos, cranial bruit and episcleral venous engorgement [2]. Fremitus, chemosis, ocular nerve palsy, increased intraocular pressure (IOP) and retinal hemorrhages may also occur, with all manifestations usually being ipsilateral to the fistula [1, 2, 4]. We report a case of a patient with traumatic unilateral direct fistula and bilateral ocular presentation.

Case Report

Ten months after a head trauma due to a road accident, a 38-year-old man presented frontal headache, low visual acuity (VA), increased volume and progressive conjunctival hyperemia in both eyes, with recent worsening. Ophthalmologic examination showed VA of count fingers in both eyes. Ectoscopy showed no pulsatile proptosis, ophthalmoparesis and bilateral chemosis were worse in the left eye (fig. 1a). Biomicroscopy showed epibulbar injection and exposure keratitis in both eyes. Tonometry was 27 mm Hg in the right eye and 28 mm Hg in the left eye. Extensive bleeding, major venous ectasia and bilateral papilledema were seen in the funduscopy and fluorescein angiography (FA) (fig. 2a–d). CT scan with contrast showed proptosis, diffuse thickening of the extra-ocular muscles and bilateral dilatation of the ophthalmic veins. Ophthalmic treatment with hypotensive eye drops and acetazolamide orally decreased levels of IOP to 18–20 mm Hg. The exposure keratitis had significant improvement with ophthalmic ointment, lubricants and eye bandage. Cerebral digital subtraction angiography (DSA) showed right high-flow CCF, Barrow Type A, venous hypertension contralateral filling of CS (fig. 3a), and bilateral ectasia of the superior ophthalmic veins (fig. 3b). Through the same right femoral artery access, the catheter was changed and the fistula was catheterized with a microcatheter. Endovascular treatment was then performed positioning detachable balloons and coils into the right CS, interrupting the arterio-venous communication. Immediate postoperative control DSA confirmed total occlusion of the fistula with patency of the ICA (fig. 3c). Postoperatively, the patient had progressive decreasing of chemosis and proptosis, with discharged 48 h after presenting a right VA of 20/80 and a left VA of 20/100 and IOP of 12/12 mm Hg, without hypotensive eye drops or acetazolamide. Ten days after the procedure, FA revealed mild right papilledema and rare bilateral microhemorrhages. After 3 weeks, the patient had a normal external examination (fig. 1b). At follow-up, 90 days after the embolization VA was 20/20, with normal IOP and funduscopy.

Discussion

The CS is a lateral sellar compartment, converging several sources of venous blood and crossed by the ICA [2]. Aquini et al. [7] described four interconnections between the CS. The widest connection in most of the cases is with the basilar plexus, present in 100% of the cases [7]. Other communications vary in size; the anterior and posterior inter-CS are always present, whereas inferior inter-CS sinus is present in 97% of the cases [2, 7].

Direct fistula typically begins by an ICA wall bursting into the CS, usually producing lesions less prone to natural closure than indirect fistulas due to high flow [1]. The ipsilateral eye is the most affected organ, ranging from mild episcleral expansion to exuberant clinical

picture, with secondary glaucoma, severe proptosis and retinal hemorrhages [1] as in this case. Bilateral presentation is usually associated with bilateral indirect CCF. Although bilateral traumatic CCF may occur in 1–2%, unilateral CCF with ipsilateral symptomatology is far more common [2]. Unilateral fistulas with bilateral symptoms are rare because despite communications between the CS, there is a major decompressive route through the ophthalmic veins [2]. Contralateral venous ectasia requires wider communication between CS, possibly associated with a specific defect in the artery wall directing the inflow to the inter-cavernous sinus.

Diagnostic imaging of CCF include CT, MR, CTAngio and MRAngio, which can show asymmetric CS widening, orbital vein and extra-ocular muscles enlargement [2]. Whereas a completely normal exam does not exclude CCF, high clinical suspicion should follow DSA, the gold standard for the diagnosis and classification [2, 8]. DSA besides identifies location, size of the fistula and venous reflux, likewise allowing immediate treatment [4].

Ideally, the treatment should be performed when the lesion is diagnosed, and prompt treatment of high flow fistulas is recommended [2, 4, 9]. Even if most of the CCF is not life threatening, venous reflux causing intracranial hemorrhage or massive epistaxis can be fatal [4, 8, 10]. Angiographic image of dilated CS with extension into the subarachnoid space and pseudoaneurysm was associated with fatal hemorrhage by Halbach et al. [4]. Increased intracranial pressure, proptosis with untreatable corneal exposure, visual deterioration, hemorrhage and transient ischemic attacks require emergent or aggressive intervention [1, 4, 11]. Treatment indications may either include diplopia, intolerable headache or bruit, secondary glaucoma and anterior segment ischemia [1].

The management of ocular symptoms may help, but the definitive treatment is focused on reducing venous pressure. Earlier, the surgical technique was based on carotid ligation, depending on the existence of collateral blood flow to maintain cerebral perfusion, later evolving to endovascular deployment of the detachable balloon [12]. Several approaches have been described: arterial, transfemoral transvenous, puncture of superior orbital vein and combined [5, 13]. The endovascular approach preserving the ICA is currently the treatment of choice for these lesions and can be performed positioning detachable balloons into the CS through the fistula [5, 13]. In addition, coils deployment is a frequently used technique and can be associated with either stents or flow diverters to avoid coil herniation [3, 6]. Fistula occlusion with covered stents is a useful method [14]. In this case, balloon deployment reduced the flow but failed to totally occlude the fistula, requiring the use of detachable coils.

The clinical improvement mainly depends on the evolution time until fistula resolution, with timely intervention avoiding irreversible neuropathies [11]. Immediate treatment as in this case allows better results, with early hospital discharge and complete patient recovery.
