Muir-Torre syndrome · Hereditary nonpolyposis colon cancer · Sebaceous carcinoma · MSH6

Abstract

Muir-Torre syndrome (MTS) is a rare genodermatosis, diagnosed by the presence of sebaceous neoplasms along with an internal malignancy, most commonly colorectal carcinomas. MTS is most commonly caused by microsatellite instabilities of the hMLH1 and hMSH2 mismatch repair genes, and is rarely caused by mutations of the hMSH6 gene. We describe the case of a 56-year-old male who presented with an enlarging mass on his back as well as hematochezia. The back mass was excised, and pathology confirmed microsatellite instability in MSH2 and MSH6. Abdominal CT and colonoscopy confirmed the presence of synchronous masses in the cecum, ascending colon, and the transverse colon. He refused any further workup or treatment, only to return 8 months later complaining of hematochezia and discomfort due to an enlarging mass protruding from the rectum. After consenting to surgical intervention, he agreed to outpatient chemotherapy treatment. The presence of sebaceous neoplasms should raise suspicion for the possibility of an associated internal malignancy.

Introduction

Muir-Torre syndrome (MTS) is an autosomal genodermatosis considered to be a subtype of hereditary nonpolyposis colorectal cancer (HNPCC), and presents with a high incidence of various internal malignancies and sebaceous neoplasms. MTS is rare, with approximately 200 reported cases [1], more commonly affecting males, with a male-to-female ratio of 3:2 [2]. Sebaceous neoplasms present at a mean age of 53 years, and visceral malignancies are diagnosed at a mean age of 50 years [3]. The underlying genetic background of MTS is attributed to microsatellite instabilities due to germline mutations in DNA mismatch repair genes, most commonly hMSH2 and hMLH1, and less commonly hMSH6, which is responsible for base substitution mutations [4, 5]. MSH6 mutations occur in 7.6% of HNPCC cases, but only in few reported cases of MTS. We present a case of MTS presenting as sebaceous adenocarcinoma of the mid-thoracic back with concurrent MSH6-positive, invasive colorectal cancer.

Case Presentation

A 56-year-old Ghanaian male with a medical history of hypertension presented to the emergency department complaining of fatigue, hematochezia, and back pain from a 7 × 7 × 4.2 cm exophytic, cauliflower-shaped, malodorous mass on his mid-thoracic back that increased in size over a period of 4 months (fig. 1a). The patient was anemic with a hemoglobin level of 7.0 g/dl, hyperglycemic with a serum glucose level of 261 mg/dl, and stool guaiac positive. He lived alone, without family contacts, and was unaware of any family history of malignancy. The back mass was excised, and pathology revealed sebaceous carcinoma with free margins (fig. 1b). CT of the abdomen showed a 9-cm segment of mass-like thickening involving the ascending colon (fig. 2a), as well as irregular wall thickening and heterogeneity in the rectum (fig. 2b). Of note, CT also demonstrated 1.7-cm adrenal nodules bilaterally. Colonoscopy with biopsy was performed, and pathology confirmed an invasive adenocarcinoma of the colon in the cecum arising from a tubular adenoma, carcinoma in situ in the ascending colon, and a tubulovillous adenoma in the transverse colon. All three tumors demonstrated microsatellite instability in MSH2 and MSH6 (fig. 3). The patient refused chemotherapy and colon resection, and was discharged after transfusion of 2 units of packed red blood cells and stabilization of his anemia. The patient was lost to follow-up.

Eight months later, he returned to the emergency department complaining of rectal bleeding for 2 days. He stated that he had had discomfort with defecation for 1 month and noticed a pink-colored mass protruding from his rectum that gradually increased in size. His hemoglobin level on readmission was 7.4 g/dl. The repeat CT results for the abdomen were relatively unchanged from those of his previous admission. The patient consented to total proctocolectomy. Intraoperatively, a careful exploration of the abdomen was manually performed and showed a large bulky tumor in the cecum, without evidence of any palpable nodal disease. Also, there was no evidence of any metastatic disease in the liver or in the omentum. A bulky rectal tumor was noted to be protruding through the anal canal and appeared to be involving the sphincter muscles. After proctocolectomy with ileostomy and omental flap, the patient recovered and agreed to outpatient chemotherapy treatment.

Discussion

MTS is diagnosed clinically, based on the presence of at least one sebaceous gland tumor associated with at least one internal malignancy [6]. The locations of skin lesions primarily observed in MTS are the head and neck, the eyelids, and the periocular region [5]. Sebaceous tumors precede visceral malignancies in 22%, occur simultaneously in 6%, and develop subsequently in 56% of the reported MTS cases [7–9]. The most common visceral malignancies occurring in MTS are colorectal and genitourinary. Therefore, some authors advocate genitourinary surveillance in addition to upper and lower gastrointestinal endoscopy for all patients with sebaceous tumors [10]. The presence of sebaceous skin lesions can support the earlier diagnosis of HNPCC in families [11]. Less commonly, the sebaceous tumors are associated with breast, hematologic, endometrial, and gastric malignancies. Previous studies have also suggested that screening for MTS should be carried out in all patients with sebaceous gland neoplasms [12]. Screening modalities may include radiological imaging, cytology, biopsies, or serum carcinoembryonic antigen levels. Abbas and Mahalingam [13] introduced a specific diagnostic algorithm based on the presence of microsatellite instabilities to identify patients with a propensity for this syndrome, as well as for the timely implementation of cancer prevention programs for patients and family members. Recent studies support the belief that mutational screening sometimes lacks sensitivity for MTS because not all mutations associated with this syndrome have been identified, and may therefore be just an additional diagnostic tool for the syndrome [6], which is diagnosed clinically.

In our case, microsatellite instability was found on MSH2 and MSH6. Although hMLH1 and hMSH2 are commonly associated with MTS, microsatellite instabilities of hMSH6 are rare. Our patient was evaluated for an internal malignancy likely because he presented with hematochezia and anemia, and coincidentally presented with a back mass which was found to be a sebaceous adenocarcinoma. However, because sebaceous neoplasms are rare in the general population, patients presenting with sebaceous tumors should be screened for visceral malignancy, including a review of systems and appropriate clinical investigations [14].

Conclusion

Whenever sebaceous tumors are identified, clinicians should consider the presence of internal malignancies. Detailed histories, particularly family histories, and physical examinations to identify masses should create a high index of suspicion, which can then be confirmed with pathology. Early recognition aids in the prompt treatment of patients, as well as screening of family members for early intervention.
