Abstract

Plexiform fibrohistiocytic tumor (PFT) is a rare mesenchymal neoplasm of intermediate malignant potential with a high local recurrence rate. In this report, we describe a case of PFT on the ear, which showed a dense deposition of periostin (POSTN) in the stromal areas of the tumor. In addition, dense infiltration of CD163+CD206– tumor-associated macrophages (TAMs) was detected in the same areas as POSTN. Since POSTN was previously reported to possess immunomodulatory effects on TAMs, our present report suggested the significance of the POSTN/TAMs axis in the progression of PFT.

Introduction

Plexiform fibrohistiocytic tumor (PFT) presents as a slowly developing nodule on the extremities and trunk [1, 2], and generally occurs in children and young adults [1, 2]. Although approximately 150 cases have been presented in English language papers about PFT [1–4], little is known about its pathogenesis.

Case Report

A 28-year-old Japanese woman visited our outpatient clinic with a 1.5-year history of an asymptomatic nodule developing on her left retroauricular skin. Her tumor had been resected by a general surgeon as a benign spindle cell tumor without further histological diagnosis 1 year before. On her initial visit, physical examination revealed a well-demarcated nodule on her retroauricular skin, 20 × 20 mm in size (fig. 1a). Magnetic resonance imaging revealed a subcutaneous nodule located adjacent to the periosteum (fig. 1b). We excised the nodule together with the adjacent periosteum with a 5-mm surgical margin. The histopathological findings revealed proliferation of fibroblastic and histiocytic cells showing storiform-type whorling and a plexiform pattern (fig. 1c, d). These tumor-composing spindle cells were positive for CD68 and SMA, and negative for S100 and factor XIIIa. The Ki67 score was approximately 10%. Based on the above finding, we diagnosed this tumor as a PFT. The differential diagnoses of PFT are listed in table 1 [2].

Since the pathogenesis and biological behavior of PFT are still incompletely understood, we employed immunohistochemical staining for periostin (POSTN), CD163 and CD206 to further investigate the possible immunological background of the PFT. A dense deposition of POSTN was detected throughout the stromal areas of the tumor (fig. 2a). In addition, CD163+CD206– tumor-associated macrophages (TAMs) were densely infiltrated in the same areas of POSTN (fig. 2b, c).

Discussion

In this report, we describe a case of PFT on the ear which showed a dense deposition of POSTN in the stromal areas of the tumor. PFT is a rare mesenchymal neoplasm of intermediate malignant potential with a high local recurrence rate, like dermatofibrosarcoma protuberans [1–4]. Immunohistochemical staining is helpful for the differential diagnosis of PFT [1, 2]: e.g. it is positive for CD68, vimentin and NSE, and negative for S100, CD34, factor XIIIa and calponin [2, 3]. Since these diagnostic markers for PFT do not reflect the biological behavior of this type of malignant tumor, in this report we employed immunohistochemical staining for POSTN as well as CD163 and CD206, focusing on the cancer stroma of PFT to investigate the possible mechanisms of local invasion and recurrence of PFT.

POSTN is an extracellular matrix protein that is involved in modulating cell functions through various pathways [5–7]. In the dermatological field, the deposition of POSTN is reported in various skin diseases, including fibrosing diseases such as keloid, hypertrophic scar [8], morphea and lichen sclerosis et atrophicus [9]. Zhou et al. [6] reported the importance of POSTN in developing glioblastoma multiforme by the induction of M2-like TAMs in the tumor microenvironment. In addition, as we previously reported, POSTN stimulates CD163+CD206– monocyte-derived macrophages to produce a series of chemokines that might be connected with the cancer formation of mycosis fungoides [7]. Notably, this study also suggests that CD163+CD206– monocyte-derived macrophages augment the mRNA expression of MMP12 by POSTN stimulation. Interestingly, MMP12 is reported to be increased in the serum and skin lesions of systemic sclerosis, and is associated with the severity of skin and pulmonary fibrosis [10]. These reports suggested the significance of the POSTN/TAMs axis in the progression of various types of tumors, and suggested that POSTN stimulation might modulate the function of CD163+CD206– TAMs to develop the fibrosis in PFT. To confirm this hypothesis, further cases and studies will be necessary.

Table 1. Differential diagnoses of PFT

	How to differentiate from PFT
Plexiform neurofibroma	S100+
Plexiform schwannoma	S100+
Cellular neurothekeoma	S100+
Fibrous hamartoma of infancy	possesses the primitive cellular myxoid component
Benign fibrous histiocytoma	solid-pattern tumor
Dermatofibroma	storiform-pattern tumor
Myofibromatosis	well-demarcated with a zoned appearance

Fig. 1. **a** A well-demarcated nodule on the retroauricular skin, 20 × 20 mm in size. **b** Magnetic resonance imaging revealed a subcutaneous nodule located adjacent to the periosteum. **c, d** Proliferation of fibroblastic and histiocytic cells showing storiform-type whorling and a plexiform pattern. Original magnification: ×100 (**c**), ×400 (**d**).
