Abstract

Benign cystic mesothelioma (BCM) is a rare benign disease that forms multicystic masses in the abdomen, pelvis, and retroperitoneum. It occurs predominantly in young to middle-aged women. The majority of cases were associated with a history of abdominal or pelvic operation, a history of endometriosis, and pelvic inflammatory disease. We present a unique case of BCM which is different to the previous cases. The patient was a 52-year-old man showing features of peritoneal carcinomatosis accompanied by ascites on abdominal computed tomography scans. We herein report a case of BCM misdiagnosed with peritoneal carcinomatosis.

Introduction

Benign cystic mesothelioma (BCM) is a very rare disease characterized by proliferative lesions of the peritoneal mesothelial cells mainly in the pelvic or abdominal cavity. However, it can also develop in the pleura, pericardium, tunica vaginalis, and spermatic cord [1]. In the past, it has also been named multicystic peritoneal mesothelioma, multilocular cysts of the peritoneum, multicystic mesothelioma, and multicystic peritoneal inclusion cysts [1, 2]. It

was first described by Menemeyer and Smith [3] in 1979 as a possible diagnosis in a case that resembled intra-abdominal cystic hygroma. Its etiology is still not definite and its pathogenesis, which is reactive or neoplastic change, is controversial. The natural course of BCM is not well known. However, its tendency to recur after partial resection is well reported. There is a case report of a patient who died from the disease 12 years after the diagnosis without treatment [4]. Therefore, the first-line treatment is complete resection whenever possible. Although intraperitoneal chemotherapy after resection is reported as treatment in a large series of patients with peritoneal dissemination of appendiceal malignancy, there still is controversy about chemotherapy [5]. BCM is often observed in women, particularly those in their childbearing age and with a history of endometriosis, pelvic inflammation, and abdominal surgery. The rate of BCM in men is 17% [4]. The disease is sometimes found in patients without any typical symptoms; however, in most cases, large masses are palpable in the abdomen and abdominal pain often accompanies the disease. The authors report the case of a BCM in a 52-year-old middle-aged male patient who showed a unique pattern in that he had ascites and had first been misdiagnosed with peritoneal carcinomatosis based on radiological examination.

Case Presentation

A 52-year-old man was admitted to our hospital due to ascites found during a medical checkup performed in a private clinic. At the time of admission, his health status was normal: blood pressure 139/86 mm Hg, pulse rate 73 beats/min, respiratory rate 20/min, and temperature 36.5°C. He had no apparent trace of the disease and was conscious. The breathing sound and the heart sound during the chest examination were normal. There was a little abdominal distension, but there seemed to be no increase in the abdominal circumference and no tenderness. In the course of the previous few months, he presented no change in weight or peripheral edema of the limbs. The peripheral blood examination showed normal findings, i.e. leukocytes 7,820/mm³, hemoglobins 14.8 g/dl, and platelets 220,000/mm³.

The biochemical test results were as follows: C-reactive protein (CRP) 0.08 mg/dl, BUN 13.2 mg/dl, creatinine 0.87 mg/dl, AST 30 IU/l, ALT 38 IU/l, total bilirubin 0.56 mg/dl, and albumin 4.3 g/dl. The tumor marker test showed normal findings, i.e. α -fetoprotein 1.8 ng/ml, carcinoembryonic antigen (CEA) 2.0 ng/ml, and carbohydrate antigen 19–9 (CA 19–9) 11.5 U/ml. Abdominal computed tomography (CT) scans presented ascites of a moderate amount. The irregularly thickened peritoneum across the abdomen and the reticular membrane in the upper left abdomen formed a mass (fig. 1). Positron emission tomography of the whole body showed no increase in the ¹⁸F-fluorodeoxyglucose uptake. The paracentesis conducted after the hospitalization resulted in an erythrocyte count of 171/mm³, leukocyte level of 288/mm³ (lymphocytes 74%), albumin level of 2.0 g/dl, protein level of 2.7 g/dl, and adenosine deaminase level of 9.5 IU/l, and there was no MTB PCR and AFB stain. As the abdominal CT findings strongly suggested peritoneal cancer, diagnostic laparoscopy was conducted.

The laparoscopic examination showed several cystic masses in the paracolic gutter forming a large mass (fig. 2a). There was much yellowish ascites, and multiple nodules of a size of 2–3 mm were widely spread in the abdominal cavity (fig. 2b). There was adhesion between the large reticular membrane and the pelvic wall. Biopsy was performed providing tissue of the size of 2 × 1.5 mm from the reticular membrane. The biopsy result showed several cysts of various sizes, which were surrounded by flat cubic epithelial cells (fig. 3a). Im-

munohistochemical staining was performed. As the biopsy did not stain for CD31 but strongly stained for calretinin and D2-40, the patient was diagnosed with BCM (fig. 3b). The patient was informed about the possible progression to malignancy and was recommended to have radical excision performed, but he preferred to wait since the symptoms were not yet apparent. We carried out an abdominal CT examination 2 months later. As there was no change in the lesion and there still was ascites, we recommended surgical treatment. However, he kept refusing it, and thus, we decided to continue monitoring the development.

Discussion

Although BCM was first referred to by Plaut [6] in 1928, it was suggested to have its origin in the mesothelial cells due to the observations made by Mennemeyer and Smith [3] using electron microscopy. Afterwards the disease could be diagnosed as soon as it had been distinguished from other diseases. After the introduction of immunohistochemistry, BCM was diagnosed when it was stained both for calretinin and D2-49 at the same time.

BCM is known to be found in women in their childbearing age. A report on the analysis of 37 patients with BCM showed that 83.8% of the patients were female and their average age was 38 years. As the disease is found in 37.8% of subjects in their 50s, in 5.3% of subjects in their 60s and in 10.8% of subjects in their 70s, as well as in infants, it is suggested that BCM may occur in patients at all ages. It is known to be more frequent in patients with a history of endometriosis, pelvic inflammation, and abdominal surgical treatment, particularly in patients having had hysterectomy and cesarean section [4].

BCM is a tumor originated from mesothelial cells in the peritoneum, pleura and pericardium. It can also appear in the groin and scrotum, which is the extension of the peritoneum. In the case of BCM in the groin and scrotum, the patients can detect palpable masses by themselves and therefore present themselves to the hospital earlier [1]. On the other hand, BCM in the abdominal or pelvic cavity is not easy to be found unless the mass is big. BCM in our case is also not easy to be detected because it is rare in a middle-aged man, and there were no specific symptoms such as palpable mass or abdominal distension. Worldwide, only 5 cases of BCM accompanied by ascites have been described so far [7]. Paracentesis results showed that his serum-ascites albumin gradient (SAAG) was 2.3 g/dl and the protein level was 2.7 g/dl, showing that the disease may be caused by cardiac ascites. Thus, when more data about BCM with ascites are available in the future, the specific features of ascites in BCM could be analyzed.

BCM can be classified into three types depending on its shape: (1) the solitary type when the boundary is clear, (2) the localized type when the multiple masses are found in the localized part of the abdominal membrane, and (3) the diffuse type when the masses are widely spread across the abdominal membrane [4]. Surgical removal is the best treatment. To prevent possible recurrence and transformation to the malignancy, it is recommended to cut out a wide enough area whenever possible [8]. Worldwide, there were only 2 cases where BCM developed into the malignancy: a baby at the age of 6 months and a female at the age of 36 years [9, 10]. Accordingly, as the rate of transformation to the malignancy is very low, re-excision is often performed even for local recurrence. In a few studies, there have been attempts to use heated intraperitoneal chemotherapy in the abdominal cavity, but this still is at an experimental stage [11].

Conclusion

BCM is a very rare disease, which is often observed in women in their childbearing age. We presented a male patient with BCM of the diffuse type accompanied by ascites and who had first been misdiagnosed with peritoneal carcinomatosis.
