Abstract

Eccrine syringofibroadenoma (ESFA) is an uncommon benign adnexal neoplasm which derives from cells of the acrosyringium of eccrine sweat glands. The clinical appearance is non-specific but the histological features are typical. Five clinical subtypes of ESFA exist: (1) solitary ESFA; (2) multiple ESFA associated with ectodermal dysplasia; (3) multiple ESFA without cutaneous features; (4) unilateral linear ESFA (nevroid), and (5) reactive ESFA associated with inflammatory or neoplastic dermatoses. We report the case of a 42-year-old man with long-standing diabetes and neuropathy, presenting with a 4-year history of asymptomatic erythematous plaques on a background of brown hyperpigmentation on the left foot. The clinical presentation and histopathological findings are compatible with reactive ESFA.

Case Report

A 42-year-old man presented with slowly progressive asymptomatic red plaques on the left foot which developed over 4 years. He was treated by topical corticosteroids with minimal improvement. He had no weight loss, prolonged fever, or night sweat. There was no family history of similar lesions. He had a 7-year history of type 2 diabetes mellitus which was treated with oral metformin and insulin injections. He had undergone amputation of the 1st, 2nd, and 3rd toe of the left foot due to neuropathic arthropathy 5 years earlier.

Physical examination revealed two discrete, well-defined, moist, macerated, erythematous, verrucous plaques on a background of diffuse red-brown discoloration on the left foot (fig. 1, fig. 2). Peripheral arterial pulses on both legs were normal and regular. There was no fever, lymphadenopathy, or hepatosplenomegaly. Other physical examinations were within normal limits. A 4-mm punch biopsy specimen was obtained from the lesion for routine histological examination.

Histopathological results showed multiple foci of thin anastomosing strands of uniform cuboidal cells emanating from the epidermis. The epithelial strands showed ductal differentiation, embedded within fibrovascular stroma (fig. 3, fig. 4). Doppler ultrasound of the left leg showed evidence of severe degree of venous reflux involving the left saphenofemoral junction and common femoral vein.

In this case, a complete excision with flap or graft was offered but the patient refused surgery. He was treated with monthly cryotherapy using liquid nitrogen spray and attended follow-ups with surveillance for malignant change. Venous stripping was performed as the treatment for severe venous reflux, which resulted in partial improvement of the lesion.

Discussion

Eccrine syringofibroadenoma (ESFA), first described by Mascaro [1] in 1963, is a rare benign adnexal neoplasm considered to originate from the excretory portion of eccrine sweat glands [2]. It typically presents in elderly patients between the 7th and 8th decade of life. The clinical manifestation of ESFA is slow-growing flesh- to reddish-colored verrucous nodules or plaques. The distribution of the lesions is most often on the extremities. Less commonly affected parts include the face, torso, buttock, nail, and peristomal skin [2, 3].

ESFA is categorized into 5 subtypes according to its clinical presentation: (1) solitary ESFA, a solitary verrucous nodule in elderly adults; (2) multiple ESFA associated with Clouston syndrome and Schöpf-Schulz-Passarge syndrome; (3) multiple ESFA without associated cutaneous findings, also referred to as syringofibroadenomatosis; (4) nonfamilial unilateral linear ESFA (nevroid ESFA), and (5) reactive ESFA associated with inflammatory or neoplastic dermatoses (e.g., erosive lichen planus, bullous pemphigoid, epidermolysis bullosa, primary cutaneous amyloidosis, burn scar, venous stasis, chronic diabetic foot ulcer, neuropathy, nevus sebaceous, and squamous cell carcinoma) [2, 4–11].

The case reported here is most likely reactive in nature, subsequent to multiple pathogenic factors including venous stasis, neuropathy, and diabetic foot ulcer, as all conditions were present at the sites of the ESFA lesions. Venous stasis was evident from the hemosiderin pigmentation on his legs. Histopathological examination and Doppler ultrasound study of the left leg also supported this finding. In addition, chronic diabetic foot ulcer would have resulted in chronic inflammation of the skin of the lower limbs, which could create the opportunity for aberrant tissue proliferation. Neuropathy may also have contributed to the

development of ESFA in this case. The mechanism by which neuropathy may be related to the proliferation of eccrine structures was postulated by Tey et al. [8]. Postganglionic sympathetic fibers are the primary innervation of eccrine sweat glands. The production of proteins (cholinergic differentiation factors and vasoactive intestinal peptide) by the sweat glands has been shown to be induced by the innervation. The neurons have also been shown to undergo developmental differentiation to decrease the production of catecholamine as a result of a reciprocal induction by the sweat glands [12]. Aberrant functions of autonomic neurons associated with long-standing diabetes could possibly alter the process of regeneration and cellular proliferation found in the eccrine tissue after injury.

The differential diagnoses include chronic eczema, warts, chronic infections (e.g., deep fungal infection, tuberculosis, and nontuberculous mycobacterial infection), benign and malignant tumors (e.g., eccrine poroma, fibroepithelioma of Pinkus, verrucous carcinoma, and squamous cell carcinoma) [7, 8].

The histological features of ESFA are diagnostic. It is characterized by anastomosing strands of thin epithelial cords, surrounded by abundant fibrous tissue [3, 9]. The epidermis shows long, thin projections, with confluent terminations similar to crab claws. The epithelial cords and strands characteristically show ductal differentiation. The tumor is usually limited to the papillary dermis. These cells may show ductal differentiation evidenced by positivity to immunohistochemical stains (e.g., CEA and BER-Ep4). The clinical course of ESFA is typically benign. Spontaneous involution has been reported in reactive ESFA [9]. Malignant transformation into syringofibrosarcoma and eccrine porocarcinoma is possible [13, 14]. However, the risk of occurrence is unknown. Metastatic disease has not been reported [7]. In addition, the coexistence of ESFA and squamous cell carcinoma has been described. Whether squamous cell carcinoma represents a malignant degeneration of ESFA or ESFA develops in response to squamous cell carcinoma is unclear [7].

The treatment of ESFA depends on the number, location, and resectability of the lesions. Solitary ESFA is treated by surgical excision. In unresectable cases, monitoring and generous sampling to rule out malignant transformation are recommended [3, 9]. Other treatment options include cryotherapy, curettage, electrodesiccation, ablative laser therapy, photodynamic therapy, radiotherapy, 5-fluorouracil, imiquimod, and topical and systemic retinoids with variable outcomes [2, 8, 15].
