Abstract

Evaluation of deep-seated lymphomas by fine-needle aspiration (FNA) can be challenging due to their reduced accessibility. Controversy remains as to whether FNA and ancillary techniques can be used to diagnose deep-seated lymphomas reliably and sufficiently for clinical management. Most published studies are favorable that endobronchial ultrasound (EBUS)/endoscopic ultrasound (EUS)-FNA plays an important role in the diagnosis of deep-seated lymphomas. The addition of ancillary techniques, particularly flow cytometry, increases diagnostic yield. While subclassification is possible in a reasonable proportion of cases, the reported rates of successful subclassification are lower than those for lymphoma detection/diagnosis. The diagnostic limitation exists for Hodgkin's lymphoma, grading of follicular lymphoma, and some T-cell lymphomas. The role of FNA in deep-seated lymphomas is much better established for recurrent than primary disease. It remains unclear whether the use of large-sized-needle FNA or a combination of core

needle biopsy and FNA improves subclassification. It is important for cytopathologists to have considerable understanding of the WHO lymphoma classification and develop a collaborative working relationship with hematopathologists and oncologists. As EUS/EBUS-FNA techniques advance and sophisticated molecular techniques such as next-generation sequencing become possible, the role of FNA in the diagnosis of deep-seated lymphomas will possibly increase.

Introduction

The evaluation of deep-seated lymphomas can be challenging. It often requires balancing diagnostic necessity versus the patient's general medical condition. Enlarged intrathoracic and intra-abdominal nodes present a unique challenge. Controversy remains as to whether endoscopic ultrasound (EUS)- and endobronchial ultrasound (EBUS)-guided fine needle aspiration (FNA) biopsy with ancillary studies, particularly flow cytometry (FC), can even be used to reliably diagnose deep-seated lymphomas such that the oncologists can proceed with appropriate clinical management.

Diagnostic Utility of EUS/EBUS-FNA

Because of their location, specimen sampling from deep-seated lesions involves image guidance. Traditional procedural options include: percutaneous computed tomography (CT)- or ultrasound (US)-guided FNA; mediastinoscopy, video-assisted thoracoscopy, or open thoracotomy for tissue biopsies of intrathoracic lesions and laparoscopy or open laparotomy for tissue biopsies of intra-abdominal lesions. The first comprehensive report on FNA diagnosis of deep-seated lymphomas (intra-abdominal and retroperitoneal), published in 1990, used percutaneous image-guided FNA [1]. All of these procedures are relatively invasive and associated with certain risks of complications. Some of these options are very costly as well.

US is one of the important discoveries of the 20th century, revolutionizing the field of diagnostic imaging [2]. Since the introduction of EUS in the early 1980s, it has progressed from a purely diagnostic tool to one that can be used to provide pathology samples (via FNA or core needle biopsy) as well as diverse therapeutic interventions [3–5]. EUS/EBUS-FNA has been shown to be a very useful, safe, and cost-effective modality for sampling deep-seated lesions. EBUS-FNA allows sampling from all bilateral mediastinal and hilar lymph node regions other than the aortopulmonary and para-aortic areas, covering a larger area than any single surgical procedure [6]. EUS-FNA is very useful for intra-abdominal and some intrathoracic deep-seated lesions in close proximity to the gastrointestinal tract, and even for deep pelvic lesions sampled through the rectum that are relatively inaccessible by other standard image-guided techniques. Small lesions, as small as 5 mm in diameter, may be biopsied using EUS-FNA, which is not usually possible using other methods, including CT-guided biopsy or FNA [7, 8]. In contrast to some of the traditional procedures, both EUS- and EBUS-FNA can be performed repeatedly for surveillance purposes. Mediastinoscopy nearly always leads to significant fibrosis; repeat procedures tend to be challenging and have a low diagnostic yield [9]. EUS/EBUS-FNA is well tolerated, avoiding exposure to radiation and general anesthesia associated with some other modalities [10–12]. Unlike many other techniques, it can be carried out in an outpatient setting using conscious sedation rather than general anesthesia. EUS/EBUS-FNA is also a safer modality compared to percutaneous CT- or US-guided FNA because of its higher spatial resolution and shorter needle tract to the target. The interposed vessels can be easily avoided by real-time imaging with EUS [13]. Cost analysis has shown that EBUS-FNA is 3- to 10-fold less expensive than mediasti-

noscopic tissue biopsy [14, 15]. The limitations of EBUS/ EUS-FNA include inaccessibility to some areas such as the subdiaphragmatic region and the difficulty in obtaining useful samples from necrotic or calcified lesions.

FNA Diagnosis of Lymphoma: Overview

A large amount of literature exists emphasizing the significance of FNA diagnosis of lymphoma [16–18]. Many have demonstrated that FNA is highly accurate in the diagnosis and subclassification of some lymphomas, particularly non-Hodgkin's lymphomas (NHLs), that surgical biopsy may not always be necessary. However, the value of FNA diagnosis of lymphoma remains controversial. More than 10 years ago, an article by Hehn et al. [19] sparked worldwide controversy. This study suggested that FNA does not usually provide reliable diagnosis and perhaps may even be misleading.

One of the most cited drawbacks of FNA diagnosis of lymphoma is the loss of tissue architecture. However, many cytopathologists argue that in the current WHO (2008) lymphoma classification [20], the diagnosis and classification of lymphomas are based not only on their morphologic features, but also on their immunophenotypic, cytogenetic, and molecular profiles. Although the architecture is still important, not all the lymphoma classifications are solely dependent on it. The immunophenotypic, cytogenetic, and molecular studies can all be performed on the aspirated material.

The second most criticized limitation of FNA diagnosis of lymphoma is inadequate sampling. Insufficient or suboptimal sampling can be due to a number of factors, including the nature and size of the lesion, experience of the operator, number of passes, size of the FNA needle, availability of an on-site evaluation, preservation technique for ancillary studies, and most importantly the workflow. Optimizing an institutionally based workflow is imperative for suspected lymphomas and requires multidisciplinary coordination among radiologists, endoscopists, pathologists, and oncologists.

Another reason behind the difficulty of an FNA diagnosis of a specific lymphoma subtype is the inherent complexity of past and current lymphoma classifications [20]. Because of this existing complexity and a continuously growing list, many cytopathologists are not familiar/ comfortable enough with the various subclassifications. Thus, it is crucial for cytopathologists to keep updated with new developments in this field and to work closely with hematopathologists and a clinical team.

FNA Diagnosis of Deep-Seated Lymphomas via EUS/EBUS, Emphasizing the Role of FC

The progress of advanced diagnostic imaging has led to the increasing detection of enlarged intrathoracic or intra-abdominal lymph nodes. EUS- or EBUS-FNA has been demonstrated to be an accurate tool for the cytological diagnosis of deep-seated lesions of unknown ori-

gin, especially metastatic epithelial malignancies [13, 21–24]. However, FNA diagnosis of deep-seated lymphoma remains controversial [6, 25, 26].

Literature Review

Table 1 summarizes 14 studies [24, 27–39] focused on the efficacy of the diagnosis of deep-seated lymphomas using EUS/EBUS-FNA from the past 15 years. A direct

comparison among these studies is not possible because each study has a unique design with different definitions of 'gold standard', different statistical measures, and variable institutional workflows; nevertheless, they provide us a general overview of/progress in this field. Overall, most studies are favorable that EUS- or EBUS-FNA, in conjunction with ancillary techniques, plays an important role in the diagnosis of deep-seated lymphomas. Two thirds of the studies were published in clinical journals, and the rest in pathology journals. The number of patients/lesions ranged widely depending on study inclusion criteria. The number of lymphomas ranged from 7 to 66, with 5 studies having >30 cases. Most studies included both nodal and extranodal sites. Most used a conventional 22-gauge needle with varying number of passes. Studies using only a 19-gauge needle or core biopsy were not included in this table. FNA smears stained with Romanowsky and Papanicolaou stain were used for cytomorphological evaluation. FC analysis was used more often (most studies) than any other ancillary techniques. Immunohistochemistry (IHC) stains were typically applied at the discretion of the cytopathologists. Cytogenetics or fluorescence in situ hybridization (FISH) was performed occasionally on selected cases (3 of 14). Molecular polymerase chain reaction (PCR) tests of B- or T-cell clonality gene arrangements were performed infrequently (1 of 14). Overall, the specificity of detection was consistently higher than sensitivity. The addition of ancillary techniques, mainly FC, increased the sensitivity considerably (84.6–87%), as well as the specificity (93–100%), compared with using cytomorphological evaluation alone (sensitivity and specificity ranging from 30.8 to 87 and from 0 to 100%, respectively) [27, 29, 37].

Rapid on-site evaluation (ROSE) was performed in almost all the studies listed in table 1. There is no doubt that ROSE not only increases the overall diagnostic yield, but also effectively helps to triage the specimen for ancillary studies [40–42]. The value of ROSE is particularly more significant for deep-seated lymphomas than for other nonhematopoietic or superficial lesions.

Cytomorphological Evaluation

Cytomorphological evaluation made from smears is the first step in the diagnostic workup of deep-seated FNA. The determination of lineage differentiation is the beginning. The distinction of epithelial, lymphoid, or other lineages is usually not difficult for experienced cytopathologists because lymphoid cells are characterized by a predominantly single-cell pattern, whereas epithelial cells typically demonstrate cohesive clusters. The presence of

abundant lymphoglandular bodies associated with predominant or lesional cells suggests a lymphoid process. In our institution, we prefer to stain smeared slides (80%) with the Romanowsky stain (Diff-Quik) if a hematopoietic lineage is determined at the time of ROSE. However, the distinction may not always be straightforward [43, 44]. Lymphoma cells may artificially show 'pseudocohesion', especially in highly cellular specimens, and some poorly differentiated nonlymphoid malignancy may show a predominant pattern of dispersion. Confounding factors such as fibrosis and necrosis as well as preparation artifacts may complicate the matter. In challenging cases, especially in the immediate evaluation, the determination should be made in correlation with clinical/radiological findings and cytomorphological features. Appropriate triage for ancillary techniques is also essential.

Ancillary Technique: FC

It has been well accepted that the addition of ancillary techniques, particularly FC, increases the diagnostic yield of deep-seated lymphomas. Among the studies listed in table 1, 12 of 14 used FC as an ancillary tool. The primary role of FC is to establish the B-lymphocyte clonality which may be difficult or impossible to do in some cases if the evaluation is based on cytomorphology alone. FC is also useful in subclassifying some lymphomas, especially when the IHC evaluation of cell blocks is not possible. FC is an imperfect tool. False-negative results are typically attributed to an insufficient amount of material, sampling error, or low viability due to the destruction of fragile cells, particularly in large-cell lymphomas. The presence of clonal B-cell populations in a nonlymphomatous process has occasionally been described where they appear to affect less than 1% of all reactive lymph nodes [45]. Aberrant expression may lead to confusion and an inability to correctly subtype some lymphomas. Opinions vary as to the indication of sending a specimen for FC and how much is enough. It is generally accepted that the aspirate material should be triaged to FC at the discretion of a cytopathologist taking into account cytomorphology, endoscopic impression, as well as clinical history. Nevertheless, some authors advocate that all specimens be sent for FC whenever there is clinical suspicion of lymphoma [26]. Nunez et al. [24] determined that two dedicated passes provided adequate cellularity (average of 5.66 million cells) for FC analysis. With the new addition of more sophisticated 8-/10-color FC machines in some laboratories, it is expected that a diagnosis of lymphoma will be rendered on fewer cells, thus making FC an even more attractive ancillary tool.

Table 2. Literature review: FNA diagnosis of deep-seated lymphomas emphasizing subclassification

Authors [Ref.], year	CJ or PJ	Lesions/ lymphomas	Primary/ recurrent	Needle size, G	Ancillary techniques	Subclassification rate, %

CJ = Clinical journal; PJ = pathology journal; NR = not reported; Sen = sensitivity.

Ancillary Technique: Others

IHC staining remains the most widely used ancillary technique when evaluating tissue sections for possible lymphoma; however, the scant cellularity and crush artifact on cell block sections may limit the use of IHC. Cytogenetics or FISH can be used to identify lymphomas with characteristic chromosomal translocations, including follicular lymphoma (FL) [t(14;18)], mantle-cell lymphoma [t(11;14)], Burkitt's lymphoma [t(8;14)], and anaplastic T-cell lymphoma [t(2;5)], for example. FISH testing can be performed on cell block sections as well as on cytology smears similar to tissue specimens [24, 46, 47]. Molecular PCR tests of B- and T-cell gene arrangement can be performed when the clonality by FC is inconclusive.

Lymphoma Subclassification Using EUS/EUS-FNA

The studies listed in table 1 demonstrate that if lymphoma is the cause of an undiagnosed deep-seated lymphadenopathy, at least its presence can be reliably detected by EUS/EBUS-FNA. However, many oncologists remain skeptical about the ability of FNA to accurately classify lymphomas and would consider an addi-

tional tissue biopsy (excisional or core biopsy) as being necessary to answer specific prognostic and treatment questions.

Literature Review

Table 2 lists 8 studies investigating the role of FNA in the subclassification of deep-seated lymphomas in the past several years after the 2008 WHO classification [13, 33, 35, 38, 39, 48–50]. Most studies were published in clinical journals. The number of lymphoma cases varied with 3 studies including more than 60 cases. Overall, the reported rates of successfully subclassified lymphomas were lower than those for the detection/diagnosis of lymphomas reported in table 1, ranging from 38 to 88.8%. These rates varied widely, likely due to significant differences in case cohorts, study designs, and confirmatory method criteria for a definitive subclassification. Most studies concluded that subclassification was possible in a reasonable proportion of cases. Nakahara et al. [13] believed the results of cytology were equal to or better than histology because of the availability of on-site evaluation and the ability to sample a wide area. However, Iqbal et al. [48] reported a very low sensitivity of 38%, suggesting that EBUS-FNA does not provide sufficient diagnostic material for subtyping. A study by Poincloux et al. [35]

concluded that the successful rate of subclassification was significantly associated with target size >30 mm.

It is mostly accepted that the role of FNA in deep-seated lymphomas seems much better established in recurrent than in primary lymphomas [33, 34, 48]. In the setting of a recurrent lymphoma, a specific subclassification is often not needed to guide therapy.

Inherent Limitations

It is clear that EUS/EBUS-FNA does not allow the diagnosis of all lymphoma subtypes with equal performance. Some lymphoma types, such as chronic lymphocytic lymphoma and mantle-cell lymphoma, encompass characteristic cytological and immunophenotypic profiles to allow for acceptable diagnosis using FNA in conjunction with appropriate ancillary techniques. Several studies have addressed the diagnostic challenge in Hodgkin's lymphoma (HL) and suggested that tissue biopsy is still the procedure of choice [13, 33, 39, 49]. First, FNA specimens from HL (especially nodular sclerosing HL, the most common type) are usually hypocellular. Secondly, FC does not play a role in the diagnosis of this particular type of lymphoma due to the lack of a clonal population. Lastly, IHC stains performed on a cell block of HL are difficult to interpret due to the limited tissue/loss of architecture, rarity of Reed-Sternberg cells, and crush artifact. All these factors may contribute to a considerable false-negative rate. Another well-reported limitation is FL grading [24, 36, 38, 51]. FL is one of the more frequently diagnosed lymphomas in deep-seated lymph nodes, and grading is considered a critical prognostic factor. Some authors state that adequate grading of FL is not possible on cytological material [19]. Differentiation between low-grade (grade 1 and 2) and high-grade (grade 3) lymphomas is clinically important and usually not difficult. The distinction between grade 1 and 2 is not easy, but it is not necessary clinically [20]. Also, differentiating large-cell transformation of a FL from diffuse large B-cell lymphoma has little clinical impact. A diagnosis of large B-cell lymphoma of follicular center origin or large B-cell lymphoma not otherwise specified may be sufficient for clinical management [52]. Caution is required when focal large-cell transformation is present. It may not be possible to distinguish between grade 2 and 3. A similar limitation applies when evaluating large-cell transformation of chronic lymphocytic/small-cell lymphomas. Of note, the side scatter value of FC analysis can aid in cell size evaluation in addition to cytomorphology. In addition, T-cell lymphomas are more difficult to diagnose and subclassify with EUS/EBUS-FNA. Although FC analysis is helpful in

identifying an abnormal T-cell population, not all T-cell lymphomas have distinct immunophenotypes. T-cell receptor gene arrangements can be helpful in determining clonality, but the test may not be readily available, and the interpretation is not always straightforward.

Role of Large Core Biopsy in Subclassification

Since the usefulness of FNA has been questioned for lymphoma subclassification due to the lack of architecture and inadequate specimen sampling, the technique of EUS-guided core needle biopsy using a larger needle size has been proposed as a possible solution. The most commonly used needle sizes for diagnostic FNA are 22 or even 25 G. The primary larger needle types on the market include conventional 19-gauge, trucut (QuickCore™), and 19-gauge ProCore™ needles. These larger needles seem to be better than smaller needles in obtaining an adequate core-tissue sample for preserving histological architecture [53–55]. They provide tissue fragments as opposed to single cells and cell groups, but require lymph nodes to be of a sufficient size to allow for sampling. The increased stiffness of the needles makes them more restrictive and difficult to maneuver [50]. Trucut needles do not perform well when the echoendoscope is not straight (e.g., duodenal bulb approach). Iglesias-Garcia et al. [53] have shown that the newer 19-gauge ProCore™ needles can overcome the drawbacks of the trucut needles. EUS-guided core needle biopsy or a combination of core needle biopsy and FNA has been shown to improve the diagnostic yield above that of FNA alone [49, 50, 56]. Gimeno-Garcia et al. [25] reviewed 5 studies that evaluated the ability of EUS-guided needle biopsy to provide adequate samples for subclassification and showed that lymphoma diagnosis was achieved in 94% of cases; subclassification according to the WHO criteria was possible in 85% of cases. The incidence of complications associated with EUS-guided core biopsy was reported to be low (2.9%). However, in a series comparing its use with FNA for a range of pathologies, no significant difference in yield was demonstrated, and one example of mediastinitis was encountered [57]. Al-Haddad et al. [27] used core needle biopsy in one of their patients, with no superiority over FNA in that case. Overall, it remains unclear whether the use of large-sized needles increases the diagnostic classification rate for lymphomas. Future technical improvements in these needles along with more evidence-based studies supporting their application in the diagnosis/subclassification of lymphomas might provide the balance we are seeking between using minimally invasive procedures and having sufficient architectural diagnostic information. It is worthwhile to note

that the current WHO defining criteria are based largely on histological findings from surgically excised specimens and not on core needle biopsies. Although a core needle biopsy or a combination of core biopsy and FNA is almost certainly advantageous in selected cases, it may still be insufficient to fully subclassify some lymphomas.

Role of Ancillary Techniques in Subclassification

While the role of FC in establishing clonality to differentiate benign reactive processes is well recognized, the role of FC in lymphoma subclassification is probably similar to or not better than IHC stains. As mentioned earlier, side-scatter analysis from FC can help to determine the size of lymphoma cells in addition to cytomorphology, which is useful in cases of large-cell transformation. Some entities characterized by specific gene expression profiles or translocations can be accurately classified based on FNA material. For example, a panel of IHC stains of CD10, BCL-6, and MUM1 can subclassify diffuse large B-cell lymphomas into germinal-center B-cell-like and activated B-cell-like origin, which has significant prognostic impact. Also, FISH translocation analysis of MYC/BCL-2 can provide diagnostic evidence for Burkitt's and 'double-hit' lymphomas. However, many entities lack such features. In the studies listed in tables 1 and 2, only occasional studies used cytogenetics/FISH. On the other hand, cytogenetic/FISH/molecular studies are not always necessary in subtyping. Mantle-cell lymphoma can be definitively diagnosed by IHC stains of BCL-1/cyclin D1/SOX-11 [58]. FISH testing (11;14) may not be necessary. The establishment of clonality by PCR gene arrangements is only needed when diagnosis is insufficient/indeterminate by cytomorphology, FC, or IHC. In the future, next-generation sequencing using FNA material may have a potential impact on classifying lymphomas [59], similar to nonhematopoietic malignancies [60]. Studies have shown that FNA material has the advantage of providing higher-quality DNA. Many studies have demonstrated that cytogenetics as well as newer molecular techniques can be performed on smear specimens [24, 46, 47].

FNA Diagnosis of Specific Organ-Based Primary Deep-Seated Lymphomas

The most commonly reported organ-based, deep-seated lymphoma type using these techniques is primary pancreatic lymphoma (PPL). PPLs are rare and represent less than 0.5% of all pancreatic neoplasms [61]. Most are intermediate or high-grade NHL, with diffuse large B-cell

lymphomas being the predominate type. They typically have a much better prognosis than adenocarcinoma of the pancreas. Because the management and outcome of PPLs are completely different from pancreatic epithelial neoplasms, accurate recognition of these rare tumors is essential. Several case series and considerable case reports have demonstrated that the diagnosis and further classification of PPLs using EUS-FNA is possible [29, 62–64].

Clinical features suggestive of PPLs include: a previous history of lymphoma, relatively young age, presence of B symptoms, large tumor size, low CA 19-9 level, and absence of jaundice. Typically, EUS shows a large heterogeneous mass [63]. Despite the larger size at presentation, it is less likely to be associated with pancreatic duct dilation and vascular invasion [62, 63]. Malignant-appearing lymphadenopathy is significantly more common in PPLs than in adenocarcinomas [62]. Similar to lymphomas elsewhere, the most important cytomorphological clue to the diagnosis is a cellular aspirate with mostly dyshesive cells with scant cytoplasm and associated with abundant lymphoglandular bodies. Necrosis and fibrosis may obscure the cellularity and cause interpretive difficulty in high-grade cases. A low-grade lymphoid process can be difficult to differentiate from inadvertently sampled lymph nodes or chronic inflammation. ROSE is essential for procurement/triage of additional material for FC, cell block, and molecular studies. Studies have shown that a combination of FC and other ancillary studies increase the sensitivity and specificity. The diagnostic accuracy is particularly improved with the addition of FC [62, 63].

In contrast to the pancreas, lymphoma is a major cause of splenic tumors [65]. Percutaneous US-guided FNA has been considered an effective and less invasive alternative to surgical splenectomy for the diagnosis of lymphoma [66–68]. However, the use of this diagnostic technique remains controversial. EUS provides a good image of the spleen through the gastric wall. Studies have demonstrated that transgastric EUS-FNA is a useful and safe tool, and may be easier than the percutaneous approach [69, 70].

Other organ-based, deep-seated lymphomas diagnosed by FNA are much less common, and the reported organ sites include liver, kidney, luminal gastrointestinal tract, and mediastinum.

Conclusion

EUS/EBUS-FNA plays an important role in the diagnosis of deep-seated lymphomas. The addition of ancillary techniques, particularly FC, increases the diagnostic

yield. While studies have shown that subclassification is possible in a reasonable proportion of cases, the reported rates of successful subclassification are lower than those for lymphoma detection/diagnosis. EUS/EBUS-FNA does not allow for the diagnosis of all lymphoma subtypes with equal performance. Diagnostic limitation exists particularly for HL, grading of FL, and some T-cell lymphomas. It remains unclear whether the use of large-sized needles or a combination of core needle biopsy plus FNA improves the subclassification. As EUS/EBUS-FNA techniques advance and more molecular techniques such as next-generation sequencing become possible for FNA material, the reliability of FNA diagnosis in deep-seated lymphomas will continue to improve.

While many general approaches to FNA diagnosis of superficial lymphomas apply equally to deep-seated lymphomas, the deep location makes it unique and challenging. Currently, most centers in North America require an excisional biopsy for suspected primary superficial lymphoma. However, for deep-seated lymphadenopathy, an FNA diagnosis of B- or T-cell lymphoma not otherwise specified may suffice for therapeutic management depending on the patient's general condition/comorbidity. Mutual collaboration and cooperation between cytopathologists and hematopathologists in the advancement of the FNA-based diagnosis of deep-seated lymphomas cannot be underestimated.
