Bipolaris hawaiiensis · Phaeohyphomycosis · Keratitis · Dematiaceous fungus

Abstract

Purpose: To report a rare case of keratitis infected by *Bipolaris hawaiiensis*. **Methods:** A patient who was diagnosed as fungal keratitis caused by *B. hawaiiensis* was retrospectively reviewed for history, clinical characteristics, risk factors, laboratory findings, treatments, and outcomes. **Results:** A 63-year-old man with a history of trauma and saw dust in the left eye presented with a corneal ulcer. Eye examination revealed whitish infiltration with a feathery edge and small brownish deposits in the anterior stroma of the left cornea. Numerous septate hyphal fragments were detected in a corneal specimen, and nucleotide sequence analysis identified *B. hawaiiensis*. Treatment was started with 5% natamycin eyedrops and oral itraconazole. Subsequently, a corneal plaque developed which did not respond to medication and debridement. The patient underwent therapeutic penetrating keratoplasty. **Conclusions:** *B. hawaiiensis* is a rare cause of corneal phaeohyphomycosis. A brownish pigmented infiltration is an important diagnostic clue, however microbiologic studies are required to obtain a definite diagnosis. Although antifungal medication and debridement are the mainstay of most corneal fungal infection, therapeutic penetrating keratoplasty can prevent morbidity related to this fungal infection.

Introduction

Fungal keratitis is a common cause of keratitis in tropical and semitropical countries [1]. Most of these infections are caused by filamentous fungi. *Aspergillus* and *Fusarium* species are the etiology of the majority of keratomycoses in many reports worldwide [2–5]. Dematiaceous fungi have increasingly obtained importance as organisms that cause corneal ulcer [6]. Species of *Curvularia* and *Bipolaris*, which belong to dematiaceous fungi, are the third most important cause of keratomycosis in many studies [6–8].

Bipolaris hawaiiensis is a darkly pigmented fungus that can cause subcutaneous, cutaneous and soft tissue diseases known as phaeohyphomycosis [9]. This organism is widely distributed in nature and most frequently related to plant material, grasses and soil. It is known to cause bronchopulmonary disease, encephalitis and subcutaneous phaeohyphomycosis [10–12], although there are a limited number of reports of ocular infection caused by *B. hawaiiensis* [13, 14]. *B. hawaiiensis* is an uncommon cause of keratitis. We report a refractory case of *B. hawaiiensis* keratitis, presenting after eye trauma, including clinical features, management, and treatment outcome.

Case History

A 63-year-old male patient reported a history of trauma to the left eye with sawdust while sawing wood 5 months earlier. The patient had underlying ocular hypertension in his right eye, but no other predisposing factors such as diabetes, topical steroid use, or immunocompromised state. He went to a secondary hospital where he was diagnosed with corneal ulcer. He was treated for fungal keratitis with 0.15% amphotericin B in the left eye and ocular hypertension in the right eye for 5 months as an outpatient. The lesion did not improve. Thus, the patient was referred to the ophthalmological outpatient department of Chiang Mai University Hospital in July 2015.

The patient complained of decreased vision and of photophobia in the left eye. Best corrected visual acuity (BCVA) was 6/6 in the right eye and 6/12 in the left eye. Eye examination revealed a whitish infiltration with a feathery edge and a brownish pigmented lesion in the anterior stroma of left central cornea. Corneal thinning, epithelial defect, mild anterior chamber inflammation, and moderate conjunctival injection were observed (fig. 1a).

After admission to the hospital, 0.15% amphotericin B was discontinued. The corneal lesion was scraped for potassium hydroxide (KOH) examination, Gram staining, calcofluor-white staining, and culture. The Gram staining showed few septate hyphae. The KOH examination and calcofluor-white staining showed numerous septate hyphae (fig. 2a, b). Confocal microscopy was performed on the left eye and demonstrated acute angle branching hyphae (fig. 2c). Fasting blood sugar was normal, and HIV antibody test was negative.

Treatment was started with 5% natamycin eyedrops hourly, 1% atropine four times per day, and 0.18% sodium hyaluronate every 4 h to the left eye. The right eye was treated with 0.5% timolol twice per day, brimonidine three times per day, and bimatoprost at night for ocular hypertension. Itraconazole (100 mg) 2 tablets daily, doxycycline (100 mg) 1 tablet twice per day, and vitamin C (500 mg) 1 tablet twice per day were prescribed for 1 week. Liver function was monitored routinely throughout the course of the treatment. The edge of the ulcer was well demarcated, indicating gradual improvement of the eye lesion. Therefore, the 5% natamycin eyedrops treatment was decreased to a frequency of every 2 h for the next 3 weeks.

The central lesion remained densely infiltrated, with an overlying superficial corneal plaque and epithelial defect (fig. 1b). Corneal debridement was done in order to remove all plaques, and the specimen was sent for KOH examination, calcofluor-white staining and culture once again. The result showed numerous septate hyphae. The result of the previous fungal culture revealed numerous dematiaceous septate hyphae of *Bipolaris* spp. (fig. 2d).

At week 5 after admission, the lesion seemed to be unresponsive to natamycin. Hence, subconjunctival injection of fluconazole (0.5 ml) was started on alternate days and 5% natamycin eyedrops was reduced to every 4 h for 2 weeks. All other medications remained unchanged.

Therapeutic corneal debridement was performed. Unfortunately, the lesion did not improve. The dense infiltrate remained, with overlying recalcitrant superficial corneal plaque. There was also an epithelial defect at the central cornea (fig. 1c). BCVA was 6/6 in the right eye and hand movement in the left eye. The corneal ulcer seemed refractory to medications. Therefore, therapeutic penetrating keratoplasty was performed (fig. 1d). A corneal specimen was sent for pathologic investigation. Special staining with Gomori methenamine silver, periodic acid-Schiff, and hematoxylin & eosin revealed septate fungal hyphae with acute angle branching (fig. 3).

On postoperative day 1, BCVA was 6/6 in the right eye and 6/60 in the left eye. Topical and systemic antifungal therapy was continued in the postoperative period. Treatment consisted of 5% natamycin eyedrops every 4 h, 0.5% levofloxacin ophthalmic solution four times per day, and 1% atropine four times per day in the left eye. Itraconazole (100 mg) 2 tablets daily was given orally for 2 weeks. Then, 1% prednisolone acetate ophthalmic suspension was started every 4 h once the infection was controlled. Within 2 weeks postoperatively, the corneal graft was clear, with no recurrence of infiltration. There were no early postoperative complications. The result of nucleotide sequence analysis identified the organism as *B. hawaiiensis*. BCVA had improved to 6/24 in the left eye 3 months after the operation. The corneal graft remained clear without recurrent infection.

Discussion

In humans, *Bipolaris* is classified as a dematiaceous or darkly pigmented fungus that causes phaeohyphomycosis [9]. It rarely infects humans. The most frequently reported species are *B. spicifera*, *B. australiensis*, and *B. hawaiiensis* [15]. Previous studies have shown that *B. hawaiiensis* can infect a variety of organs [10–12]. The case reports of corneal ulcer caused by *B. hawaiiensis* are few because *B. hawaiiensis* is an uncommon cause of keratitis. One has been reported in a leprosy patient by Anandi et al. [14] and another in an immunocompetent patient by Bashir et al. [13].

This case of *B. hawaiiensis* keratomycosis was found in Thailand, a tropical country like India, in both of which *B. hawaiiensis* keratomycosis has been reported previously [13, 14]. The predisposing factor of this case, a male with outdoor trauma, is in accordance with Garg et al.'s [6] report of the most common predisposing factor for dematiaceous fungal keratitis. It is possible that *B. hawaiiensis* is widely distributed in plants or soil. Therefore, it could infect humans by contact with contaminated plant debris, wood or soil. The clinical features of this case, namely the whitish infiltrate with a feathery edge in the anterior stroma of the central cornea and brownish pigmented lesion, look no different from those reported by Garg et al. [6], who found yellow-white infiltrate with dry, raised slough and feathery edges in most cases of dematiaceous fungal keratitis. However, this case developed a whitish cor-

neal plaque as the specific characteristic, which was previously reported with rare organisms [15, 16]. The recalcitrant corneal plaques may prevent the penetration of drugs. On the other hand, corneal plaques seemed to simultaneously strengthen the corneal stroma and prevent perforation of the cornea. In addition, the previous misdiagnosis as yeast and inappropriate treatment caused a delay in appropriate treatment. KOH examination and calcofluor-white staining revealed numerous septate hyphae. Fungal culture showed dark septate hyphae with numerous conidia of *Bipolaris* spp. Nucleotide sequence analysis confirmed the diagnosis of *B. hawaiiensis*.

The authors encourage clinicians to perform more specific mycological evaluations of these pigmented fungi to better define their roles in fungal keratitis. Thorough evaluation and accurate diagnosis will lead to the appropriate treatment. In this case, topical natamycin was initially started. The manifestation of the whitish corneal plaque complicated the treatment. Although use of topical natamycin has been reported to be successful in treating most dematiaceous fungal keratitis [6], this case did not respond to topical natamycin and corneal debridement. Beside natamycin, nystatin ointment [14] is another treatment for *B. hawaiiensis*. Unfortunately nystatin ointment is not available in Thailand. Subconjunctival fluconazole injection [15] was attempted, but unfortunately the lesion did not improve. Eventually, therapeutic penetrating keratoplasty was required.

Considering penetrating keratoplasty in infectious keratitis, the advantages include the ability to remove infected and inflamed corneal tissue unresponsive to medical treatment, shortened hospitalization and rapid improvement in visual acuity. However, the disadvantages that need to be addressed are the risk of corneal graft failure, recurrent infectious keratitis in case of total involvement of corneal ulcer, the high incidence of graft failure, and the risk of glaucoma due to topical steroid use [17].

In this study, we report the success of therapeutic penetrating keratoplasty in treating *B. hawaiiensis* keratomycosis which did not respond to medications, and conclude that therapeutic penetrating keratoplasty should be considered to remove the infected corneal tissue and recalcitrant corneal plaque and to improve visual acuity in refractory *B. hawaiiensis* keratomycosis.

Conclusion

B. hawaiiensis is a virulent organism which can cause ocular morbidity and blindness. Early diagnosis and accurate identification of the pathogenic *B. hawaiiensis* can lead to prompt and appropriate treatment and prevent ocular morbidity and blindness. In refractory *B. hawaiiensis* keratomycosis, therapeutic penetrating keratoplasty should be considered to remove the infected corneal tissue and recalcitrant corneal plaque and to improve visual acuity.
