Subretinal abscess · Optical coherence tomography · Fundus autofluorescence · Miliary tuberculosis

Abstract

This case report describes the features of a tuberculous subretinal abscess in a non-HIV patient. It includes the characterization of the lesion with spectral-domain optical coherence tomography (SD-OCT) and fundus autofluorescence examination. SD-OCT and autofluorescence imaging showed external retinal involvement during development of the tuberculous subretinal abscess. Patients with tuberculous lesions need a multidisciplinary approach, since the disease may involve any part of the body. In this case in particular, incidental findings at computed tomography scan led to the detection of this rare ocular manifestation of tuberculous disease.

Introduction

Tuberculosis (TB) is a granulomatous disease caused by *Mycobacterium tuberculosis*, which currently remains a worldwide health problem, especially in endemic countries and in patients undergoing any kind of immunosuppression [1]. In 2014, 9.6 million people have fallen ill and 1.5 million people died of TB [2].

Ninety percent of infected people are asymptomatic, while among those who develop the disease, close to 80% have pulmonary manifestations. Only 20% of the patients have an extrapulmonary disease. Ocular TB is a rare disorder. In cases with ophthalmic involvement, any part of the eye or the orbit can be affected. Posterior uveitis is the most common ocular presentation, particularly multiple choroidal tubercles [1].

We report a case of a young male with disseminated miliary TB who was referred to us because of the incidental finding of a tuberculous subretinal abscess in his left eye when a brain computed tomography (CT) was performed.

Case Report

A 24-year-old man was admitted to our hospital with major complaints of weight loss, asthenia, and a precervical mass during the last month. He had a family history of 2 of his relatives, who lived with him in an extremely poor environment, undergoing anti-TB medical treatment. A fine-needle aspiration biopsy of the mass was performed, and the Ziehl-Neelsen stain was positive for acid-fast bacilli. He was diagnosed as having scrofuloderma in the context of lung miliary TB. Bacilloscopy was negative on 3 occasions during hospitalization. Immunological status was assessed without remarkable results, and HIV test was negative. The patient, who had a nonbacilliferous TB, was started on treatment with isoniazid, rifampin, pyrazinamide, and ethambutol and, therefore, he was discharged after 1 week of hospitalization to continue ambulatory treatment.

Notwithstanding, he came back 3 weeks later with acute paraparesis. Clinical examination revealed prevertebral cervical and lumbar abscesses, and an urgent laminectomy was performed. His tuberculin skin test (5 tuberculin units/0.1 mL) was highly positive (20 × 25 mm), and his HIV screening remained negative. A severe malnutrition with a body mass index of 17 together with an important decrease in hematocrit and plasma proteins were observed. During his hospitalization, he continued with the standard 4-drug regimen for TB treatment. A pan-computed tomography detected hepatic abscesses, pleural effusion, pulmonary miliary TB, a brain abscess in the frontal lobe (Fig. 1), and a mass in the left eye (Fig. 2). The latter finding led to a consultation at our service.

At ophthalmic examination, the patient had a best-corrected visual acuity of 20/20 in OD and counting fingers in OS. Anterior segment examination had no remarkable signs. Dilated funduscopy showed a solitary yellowish elevated choroidal lesion involving the optic disc in OS. Next to the lesion, peripapillary and macular folds were observed. The longest diameter of the lesion was 6 DD (Fig. 3).

An spectral-domain optical coherence tomography (SD-OCT; Spectralis, Heidelberg) was performed of the lesion (Fig. 4), where a hyperreflective choroidal mass with a hyporeflective center was seen. The line of retinal pigment epithelium/Bruch's membrane complex was disrupted, with a hyperreflective substance located in the subretinal space. A subretinal fluid over the hyperreflective substance could be seen, with membranous structures dividing the subretinal space into several compartments. The macula was uninvolved, although nasal

retinal folds and a posterior hyaloid detachment nasally to the fovea were observed. Fundus autofluorescence revealed a hypoautofluorescent area corresponding to the tuberculoma, surrounded by a hyperautofluorescent perilesional halo (Fig. 5).

Based on the clinical examination and the images of the patient, the most likely presumptive diagnosis was a tuberculous subretinal abscess. Therefore, the decision was to continue with the 4-drug regimen for TB to complete a 3-month period and then with 2 drugs for an additional 9 months.

After 6 months of TB treatment, the abscess had decreased in size to form a flat and pigmented scar (Fig. 6). However, the visual acuity of his left eye remained without change, and he developed a remarkable exotropia. During a 2-year period of follow-up, the lesion remained inactive without further changes.

Discussion

Tuberculous subretinal abscess is an infrequent presentation of ocular tuberculosis. It develops from liquefaction necrosis from caseous material of large tuberculomas [3]. Tuberculomas can be seen in patients with miliary TB [4–7], tuberculous central nervous system involvement [8–10], TB of the spine [4], and immunosuppressed patients [11, 12]. It has also been reported in association with AIDS, and a minimal inflammatory reaction may be observed when it occurs [13]. Tuberculous subretinal abscesses have been described in HIV/AIDS [14] but also in immunocompetent patients [15]. In the case described in this report, involvement of multiple organs occurred, including pulmonary miliary tuberculosis and paravertebral, brain, and liver abscesses.

Abscesses are more yellow than choroidal tuberculomas and often have overlying retinal hemorrhages. In patients with disseminated tuberculosis, these lesions can be associated with slight overlying vitreal inflammation [1, 3].

There is 1 description of OCT for a tuberculous subretinal abscess. In a case report of a peripapillary subretinal abscess associated with posterior scleritis, OCT showed gross disk edema and cystoid macular edema [15]. However, there is no description of the external retinal and choroidal damage as in our case. According to the features observed on the OCT images of our patient, we can infer that the former choroidal lesion disrupted Bruch's membrane and the pigment retinal epithelium, invading the subretinal space. Subretinal membranous structures likely correspond to fibrin formation, dividing the subretinal space into several compartments.

To our knowledge, currently, there are no reports on fundus autofluorescence imaging for tuberculous subretinal abscesses. The hypoautofluorescence observed at the surface of the subretinal abscess may be caused by the inflammatory destruction of the retinal pigment epithelium and the presence of a subretinal inflammatory exudate.

As a conclusion, these patients need a multidisciplinary approach, since the disease may involve any part of the body. In this case in particular, incidental findings on CT scan led to the detection of this rare ocular manifestation of the disease. OCT and autofluorescence imaging showed the external retinal involvement during the development of the tuberculous subretinal abscess.
