Abstract

Necrolytic acral erythema (NAE) is a distinctive skin disorder. The exact cause and pathogenesis is still unclear. Most studies report an association of NAE with hepatitis C virus (HCV) infection. We report a 64-year-old woman who presented with chronic mildly pruritic brownish to erythematous rashes on both lateral malleoli for 7 months. The clinical and histopathological findings were compatible with NAE. However, the serologic marker for HCV was negative.

Case Report

A 64-year-old woman developed mildly pruritic brownish to erythematous rashes on both lateral malleoli for 7 months. She had been diagnosed with lichen simplex chronicus and treated with several types of topical steroids, namely 0.05% clobetasol propionate ointment and triamcinolone acetonide 10 mg/mL injection, with minimal improvement. There was no history of significant weight loss or trauma on the affected area. She was otherwise healthy. Physical examination revealed bilateral well-defined brownish hyperkeratotic

ic plaques with an erythematous rim located on both lateral malleoli (Fig. 1). The scalp and nails were normal. Other physical examinations were unremarkable.

A 4-mm punch biopsy was performed on the left malleolus for routine histological examination. The finding revealed papillated psoriasiform epidermal hyperplasia, compact hyperkeratosis, and mounds of parakeratosis with neutrophils. There were pale and vacuolated keratinocytes in the superficial epidermal layer and scattered necrotic keratinocytes. The granular layer was absent. Dense inflammatory cell infiltrate was composed mainly of lymphocytes. Extravasated erythrocytes with dilated capillaries in the papillary dermis were also observed (Fig. 2, Fig. 3). The histological findings were consistent with necrolytic erythema.

Laboratory finding including anti-hepatitis C virus (HCV) as well as hepatitis B surface antigen and antibody were negative. Her fasting blood sugar was 107 mg/dL and her plasma zinc level was 81 µg/dL (normal 70–120 µg/dL).

The patient was treated with oral zinc sulfate 220 mg/day, doxepin 25 mg/day, and combined 0.05% betamethasone dipropionate/3% salicylic acid ointment twice a day for 1 month. There was no clinical improvement with this regimen, hence the zinc sulfate dose was increased to 440 mg/day, with partial improvement.

Discussion

Necrolytic acral erythema (NAE) was first described in 1996 by el Darouti and Abu el Ela [1]. It is almost exclusively associated with HCV. However, some cases of NAE have been reported in the absence of HCV infection [2–6]. There was 1 report of NAE following hepatitis B virus vaccination [7]. Its pathogenesis is still unknown. However, it is thought to be related to zinc dysregulation, which can occur as a result of HCV-induced metabolic alteration [8]. NAE is associated with decreased zinc levels in both the serum and the skin [9]. Characteristic features of NAE include sharply marginated scaly erythematous to hyperpigmented plaques predominately on lower extremities [10]. The most common NAE locations are the feet, follow by the lower legs, knees, thighs, genitalia, buttocks, and abdomen. Involvement of the upper extremities is generally mild and limited. The head and neck, palms, soles, nails, and mucous membrane are usually spared [10]. NAE manifests with several stages of involvement. In the initial stage, patients present with scaly erythematous papules or plaques which are deep red to violaceous at the center. Sharply demarcated scaly erythematous to violaceous lichenified plaques can be found in fully developed lesions. Superficial epidermal necrosis is occasionally observed over the dusky portions of the lesion. The pruritic plaque may remain unchanged for months. In the late stage, the lesions become progressively thinner, with some crusting and erosion. NAE is a chronic relapsing and remitting disease, and spontaneous exacerbation can be expected [10].

The differential diagnosis of NAE includes chronic eczema, psoriasis, necrolytic migratory erythema, acrodermatitis enteropathica, and pellagra. This can be differentiated by clinical presentation or histological and laboratory examination.

The histological findings are similar to those of necrolytic erythema characterized by initially acanthosis, epidermal spongiosis, and superficial perivascular dermatitis. Fully developed NAE exhibits psoriasiform hyperplasia and prominent papillomatosis with parakeratosis, subcorneal pustules, epidermal pallor, and necrotic keratinocytes. Confluent necrosis of the keratinocytes in the upper parts of the epidermis may lead to cleft formation. Vascular ectasia, papillary dermal inflammation, and pigment incontinence are also seen [11]. The

presence of foci of epidermal dyskeratosis and pale keratinocytes helps to differentiate NAE from psoriasis.

Our patient's histological findings were consistent with necrolytic erythema. She had negative serology for HCV infection and a normal plasma zinc level. However, we did not evaluate glucagon, niacin, and biotin levels due to limitation in laboratory processing. Dermatitis of niacin deficiency usually presents in photoexposed areas and may be accompanied by diarrhea and dementia. However, these features were lacking in our patient. She denied any history of weight loss and was generally well; her fasting blood sugar level was within the normal range. Therefore, glucagonoma characterized by glucagon overproduction was less likely. Acquired zinc deficiency, which manifests as eczematous rash preferentially on acral and periorificial sites, is indistinguishable from NAE histologically. Given the normal zinc level, acquired zinc deficiency was the less likely diagnosis in this patient.

The treatment of NAE is difficult, as it is frequently resistant to most topical and systemic agents. Available treatment options are mainly reported in case reports or small case series. Complete or partial resolution has been demonstrated in HCV-associated NAE with interferon alpha-2b and/or ribavirin [12]. Topical corticosteroids result in transient improvement. Systemic corticosteroids showed inconsistent benefit, ranging from no response to complete resolution [12]. The benefit of intralesional triamcinolone acetonide could not be proven. Oral zinc supplementation at a dose of 220 mg twice a day showed a variable response rate, from no response at all to near-complete response [12]. Improvement of NAE after zinc supplementation has been reported in patients with both low and normal zinc levels [12]. Topical tacrolimus together with the combination of zinc, vitamin B1, and vitamin B6 has offered complete resolution in some reports [12, 13].

We present an unusual case of NAE without HCV infection. Although it is rarely reported, NAE should be included as a differential diagnosis in patients presenting with chronic lichenified plaque on the lower extremities.
