What Is It about?

This study compares topical antibiotic intratracheal treatment between two novel preparations composed of exogenous porcine surfactant plus polymyxin B with addition of polymyxin E using an animal model of neonatal *Escherichia coli* pneumonia. Lung function, survival, pulmonary bacterial growth, and bacterial translocation are studied. Furthermore, histopathology and proinflammatory IL-8 were compared between the treatment groups.

Keywords

Neonatal pneumonia · Pulmonary surfactant · Polymyxin · Pulmonary inflammation · Rabbit pups

Abstract

Background: Ascending maternofetal bacterial infections often result in premature birth and neonatal respiratory distress. These neonates are treated with exogenous pulmonary surfactant (SF) and systemic antibiotics. Polymyxins are antimicrobial peptides that may bind to SF phospholipids. **Objectives:** Does topical administration of SF/polymyxin reduce bacterial growth in neonatal rabbit pneumonia and improve pulmonary function? **Methods:** Neonatal rabbits were tracheotomized and treated intratracheally with mixtures of porcine SF, SF/polymyxin E (PxE), or polymyxin B (PxB). Control animals received saline. Animals were then inoculated with *Escherichia coli* and ventilated for 4 h. During the experiment, peak insufflation pressures, dynamic lung compliance, and ECG were recorded. Pulmonary and renal bacterial load were determined. Lung histology was performed. Lung and kidney IL-8 were measured in subgroups. **Results:** Eighty-five animals were included in 2 experimental series, of which

78% survived 4 h of ventilation. *E. coli* inoculation caused severe neonatal pneumonia with median IL-8 levels of 2.2 ng/g in the lungs compared to a median of 0.2 ng/g in the lungs of the saline controls ($p < 0.01$). Lung compliance after 4 h was significantly increased at a mean of 0.48 ml/(kg · cm H₂O) in the SF group and 0.43 in the SF + PxE group compared to 0.35 in the *E. coli* group ($p < 0.01$). In direct comparison, bacterial growth found in the *E. coli* group was reduced 20-fold in the SF + PxB group compared to 75-fold in the SF + PxE group. **Conclusion:** Addition of polymyxin to SF effectively promotes antimicrobial treatment and improves lung function in neonatal pneumonia of rabbits.

Introduction

Bacterial pneumonia is life-threatening in neonates. Gram-positive group B streptococci and Gram-negative *Escherichia coli* are the most abundant pathogens in early-onset sepsis [1]. Subsequently to maternal premature rupture of the membranes, ascending bacteria can reach the conducting airways that promote the second largest epithelial surface to the outside environment [2–4].

Due to respiratory distress and risk of infections, neonates are often treated with antibiotics and exogenous surfactant (SF). Epithelial airway damage, SF deficiency, and inflammation may cause a vicious cycle that ultimately ends in perpetuation of respiratory distress, sepsis, and bronchopulmonary dysplasia.

Polymyxins are antibiotics with a cyclic polycationic antimicrobial lipopeptide structure [5]. Due to neurotoxic and nephrotoxic side effects, polymyxins are mainly used for topical therapy.

The use of SF as a vector for topical pulmonary drug administration is a concept that has been evaluated for mixtures with antibiotics [6, 7], including polymyxin B (PxB) [8]. Polymyxins and SF-specific proteins B and C have some similar properties. Thus, we hypothesized mutual functional support in polymyxin-SF mixtures.

In the present study, we focused on prophylactic treatment of mixtures composed of SF and polymyxin E (PxE) versus PxB in neonatal rabbit pneumonia.

Methods

Surfactant Preparations

Poractant alpha (SF, Curosurf®, Chiesi Farmaceutici, Parma, Italy) is a modified porcine SF at a phospholipid concentration of 80 mg/mL. PxE sulfate (Colistin sulfate salt, Sigma Aldrich; No. C4461) or PxB sulfate (Sigma Aldrich No. P1004) were suspended in saline at 20 (PxE) or 80 mg/mL (PxB or PxE) and mixed with SF at a ratio of 1:100. The resulting phospholipid concentrations were 79.2 mg/mL in the PxB- or PxE-containing preparations which is close to the original SF preparation of 80 mg/mL. The polymyxin concentrations were 0.2 or 0.8 mg/mL.

General Animal Model

Frozen *E. coli* aliquots, ATTC 25922, were recultivated for 16 h in bouillon (7882; Merck, Darmstadt, Germany), subsequently transferred into new bouillon for 1 h to reach a mid-logarithmic growth phase and washed, and then the stock was adjusted to $\sim 10^8$ colony-forming units (CFU)/mL using a spectrophotometer. A viability count confirmed the specific concentration.

Pregnant New Zealand White does were kept in an appropriate environment with a sufficient supply of food and water.

At the gestational age of 29 days (term gestation 31 days), the does were anesthetized using diazepam and fluanisone/fentanyl. Up to 9 pups were born by cesarean section, anesthetized using pentobarbital sodium, and tracheotomized. Subsequently, the animals were treated intratracheally, positioned in a warm plethysmograph (37°C), relaxed by pancuronium bromide, and connected to the ventilator and the ECG. Lungs were opened by 5 inspirations at peak insufflation pressures (PIP) of 35 cm H₂O, a frequency of 40/min, and an inspiration:expiration ratio of 1:3 at 100% oxygen. PIP was reduced corresponding to individual tidal volumes of 6–7 mL/kg body weight (bw). Plethysmographic individual tidal volumes and PIP were recorded before inoculating bacteria (15 min), at 30 min, and then every 30 min until 4 h. Compliance was calculated by dividing the tidal volume by the corresponding PIP and the body weight. Death was considered when ECG showed heart frequencies below 100 bpm. After 2 h of additional pentobarbital, pancuronium bromide and glucose 10% were given.

Experimental Series

We performed 2 experimental series. The SF dose was 200 mg/kg bw. The “Px series” was comprised of 5 treatment groups: the saline control and *E. coli* groups received 2.5 mL/kg bw saline, and the SF, SF/PxE 1% and SF/PxE 0.25% groups received the corresponding volume of each SF preparation. The “Px versus PxB series” was composed of an *E. coli*, SF, SF/PxE 1%, and SF/PxB 1% group at an identical setting. With the exception of the saline control group in the “Px series,” all animals were inoculated with *E. coli* at 15 min.

Sample Preparation

Animals were killed by intracerebral injection of lidocaine 2%. The kidneys were excised and the thorax was inspected for evidence of pneumothorax. In the “Px series,” we determined the bacterial load of the left kidney and the right lung. The left lung was processed for histology. In the “Px versus PxB series,” the left main bronchus was tied and the left lung was excised and divided in a central part for histology and a peripheral part for determination of bacterial load. The remaining right lung underwent bronchoalveolar lavage for future analysis.

All samples were weighed.

Histology

Lungs were fixed for 24 h in 4% buffered formalin and embedded in paraffin, and large transversal sections of 3–5 µm thickness were stained with hematoxylin/eosin. Semiquantitatively, alveolar air expansion was estimated by a 5-grade scale (0, 1–25, 26–50, 51–75, 76–100%), airway epithelial necrosis by a 4-grade scale (absent, mild, moderate, prominent), and inflammation and pulmonary hemorrhage by a 3-grade scale (absent, moderate, prominent).

Homogenization

Samples were washed twice, normalized at a weight of 1 g (kidney) or 1.5 g (lung) by adding saline, and homogenized at 30,000 rpm using sterile tips (Omni TH; Omni International, Marietta, GA, USA).

Bacterial Load

Aliquots of homogenized (left) kidneys and serially diluted lung homogenates were transferred to Petri dishes and mixed with warm Columbia agar base (Oxoid CM 331–550 g)

containing 5% defibrinated sheep blood. Dishes were incubated for 24 h at 37°C and the average count from duplicates showing 0–250 CFU/dish was considered for analysis.

Interleukin ELISA

Homogenates were stored on ice until centrifugation at 3,000 *g* for 10 min. IL-8 was determined in supernatants of 42 right lung and 37 right kidney homogenates using a sandwich enzyme immunoassay kit (SEA080Rb; Cloud-Clone Corp., Houston, TX, USA). If needed, samples were diluted in phosphate-buffered saline.

Statistical Analysis

Statistical analysis was performed using the GraphPad Prism package (4.02; GraphPad Software, La Jolla, CA, USA). For nonparametric bacterial growth and semiquantitatively assessed histology data, Mann-Whitney tests were performed. Survival was compared using χ^2 tests. All other data underwent *t* tests.

Results

General Observations

In the “Px series,” 51 neonatal rabbits with a mean birth weight of 41.5 ± 7.5 g were obtained ($n = 8–11$ /group). The mean *E. coli* stock concentration was 4×10^8 CFU/mL. Three animals that died during initial treatment were excluded. During ventilation, an additional 12 (25%) animals died. We found no differences in the weight of the right lung.

In the “Px versus Px series,” 41 pups with a mean birth weight of 44.3 ± 5.3 g were treated ($n = 8–10$ /group). The mean *E. coli* stock concentration was 2×10^9 CFU/mL. Four animals were excluded from analysis: 2 died during initial treatment, 1 developed pneumothorax, and 1 had tracheal cannula dislocation. During ventilation, 7 animals (18%) died.

In both series, we found no statistical differences regarding birth weight or survival.

Lung Function

Overall, dynamic compliance was between 0.36 and 0.55 mL/kg $\times$ cm H₂O (mean) and tended to decrease during ventilation. However, the differences in lung compliance within each series were too small for providing significance values.

First, a combined analysis of surviving animals from both series revealed an increased dynamic lung compliance (mean $\pm$ SD [mL/(kg $\cdot$ cm H₂O))] after 4 h of ventilation in SF- (0.48 ± 0.13) and SF + Px-treated animals (0.43 ± 0.08) compared to the *E. coli* group (0.35 ± 0.09 ; $p < 0.01$).

Microbiology

In the “Px series,” the pulmonary bacterial load of the *E. coli* and SF groups was similar (median log₁₀ ~8.5 CFU/g lung). In comparison, treatment with SF + Px (0.25 or 1%) significantly reduced the bacterial load by 2 log-steps ($p < 0.01$; Fig. 1). A comparison of the bacterial concentration stratified to each experimental day with pups from identical does showed a 33-fold reduction of SF + Px-treated animals compared to SF-treated pups. Similarly, in the “Px versus Px series,” the bacterial load of the *E. coli* and SF groups were 8.8 and 8.5 CFU/g lung (median log₁₀), respectively, which also was significantly reduced by 2–3 log-steps after addition of 1% Px or Px (Fig. 2). In direct comparison, again stratified to each experimental day using results of pups from identical does, SF + Px treatment gave a 75-fold reduction of bacteria per g lung compared to a 20-fold reduction in SF + Px-treated animals.

Fig. 1. Bacterial load in lungs of the polymyxin E (PxE) series. Scattergram of $\log_{10}$ of the bacterial load in lungs of Px series after 4 h of ventilation of neonatal rabbits treated initially with intratracheal surfactant (SF), SF plus 0.25% or 1% polymyxin E (SF/PxE), or saline (saline, *Escherichia coli*). With the exception of the saline group, all animals were inoculated at 15 min of ventilation with *E. coli*. Bars show medians of 8–11 animals per treatment group. ** $p < 0.001$ vs. *E. coli* and SF.

Fig. 2. Bacterial load in lungs of polymyxin E (Px) versus polymyxin (Px) series. Scattergram of $\log_{10}$ of the bacterial load in lungs after 4 h ventilation of neonatal rabbits treated initially with intratracheal surfactant (SF), SF plus 1% polymyxin E (SF/PxE 1%; w/w) or SF plus 1% polymyxin B (SF/PxB 1%; w/w), or saline (*Escherichia coli*). After 15 min of ventilation, all animals received *E. coli* bacteria. Bars show medians of 7–10 animals per group surviving treatment >30 min. ** $p < 0.01$ vs. *E. coli* and SF; † $p < 0.05$ vs. SF/PxB 1%.

Bacterial translocation to the kidney was found in 8 of 10 surviving animals of the *E. coli* group in the “Px series,” in 3 of 9 animals treated with SF, and in 2 of 8 animals treated with SF/PxE 0.25%, but only in 1 of 10 animals treated with SF/PxE 1% ($p < 0.01$ vs. the *E. coli* group). In the “Px versus PxB series,” we only found bacterial translocation to the kidney in the *E. coli* ($n = 3$) and SF groups ($n = 2$), without statistical significance.

Histology

In the saline group, alveolar air expansion was found at a median of 2, i.e. between 26 and 50%, ranging from 1–75% (Fig. 3a). After SF $\pm$ polymyxin treatment (Fig. 3c), this parameter increased to values above 25% with a median equivalent to 26–50% ($p < 0.05$ vs. saline). The *E. coli* group showed the most heterogenous alveolar air expansion giving a full range of semi-quantitative assessment (median equivalent to 26–50%; for example see Fig. 3b). Combined statistical analysis of both series showed that alveolar air expansion was significantly higher in animals treated with SF $\pm$ polymyxin compared to saline controls or *E. coli* ($p < 0.05$). All

Fig. 3. Representative histologic lung sections. Representative images of transversal histologic lung sections stained with hematoxylin-eosin of neonatal rabbits treated with saline (**a**), *Escherichia coli* (**b**), surfactant and subsequently *E. coli* (**d**), or SF/polymyxin B 1% followed by *E. coli* (**c**). Animals exposed to saline and only *E. coli* are nearly collapsed (**a**, **b**), whereas those treated with SF $\pm$ polymyxin showed a higher degree of alveolar air expansion (**c**, **d**). Prominent histological inflammation including neutrophil influx and plugging of small airways (*) with conglomerates composed of neutrophils, bacteria, and erythrocytes was found in all treatment groups receiving bacteria (**b–d**). Additionally, prominent lung hemorrhage was found in SF/PxB-treated animals († **c**).

animals inoculated with bacteria showed a high degree of pulmonary inflammation with no statistical differences between the groups (Fig. 3b–d). Inflammation was also found in the saline group, but at a significantly lower level compared to the *E. coli* group (Fig. 3a). Prominent pulmonary hemorrhage was found in the PxE versus PxB series at 30% in the *E. coli* group, 13% in the SF group, at 20% in the SF/PxE 1% group, and at 56% in the SF/PxB group ($p < 0.05$ vs. SF/PxE 1%). In the SF/PxE group of the Px series, no severe pulmonary hemorrhage was found.

Proinflammatory Markers

A linear regression analysis of IL-8 levels versus survival time showed a significant deviation from a slope of zero for the saline group, but not for *E. coli*-treated animals. Thus, IL-8 increases significantly during ventilation in dead animals. Considering survivors, IL-8 was significantly increased in all animals treated with *E. coli* (median 2.2 ng/g lung; IQR: 1.6–4.0) versus the saline group (median 0.22 ng/g lung; IQR: 0.15–1.1; $p < 0.01$; Fig. 4). Values in groups treated with *E. coli* $\pm$ SF $\pm$ Px did not vary significantly from each other.

Kidney IL-8 levels of survivors showed no statistical differences.

Fig. 4. IL-8 levels in lung homogenates. IL-8 levels in homogenates of right lung of neonatal rabbits surviving 240 min of ventilation after initial treatment with surfactant (SF), SF plus different amounts of polymyxin E (SF/PxE 0.25% and SF/PxE 1%), or saline (saline or *Escherichia coli* group). With the exception of the saline group, all animals received *Escherichia coli* intratracheally at 15 min of ventilation. Scattergram of 5–7 repeated measurements. Bar = median; ** $p < 0.01$ vs. saline.

Discussion

This is the first study comparing intratracheal treatment of modified porcine SF + PxE versus PxB in an in vivo model of neonatal pneumonia.

We previously showed that addition of PxB to porcine SF in vitro resulted in maintained antimicrobial activity and improved surface activity [8]. In addition, PxB accelerates SF exocytosis in isolated cultured rat alveolar type II cells [9]. However, neither an improvement nor a deterioration of lung function could be found by comparing the compliance data of animals treated with only SF with those treated with SF plus admixed PxE or PxB.

For treatment of acute inflammatory lung injury, SF must have the greatest possible activity and resistance to inactivation [10]. Often, repeated high SF doses are needed to overcome inhibition as shown in premature neonates with culture-positive bronchoalveolar lavage [11]. The study underlines that high SF doses improve lung function in injury due to bacterial pneumonia: animals treated with SF or with SF + PxE each at 200 mg/kg had significantly increased compliance compared to the *E. coli* group. This is in line with the finding that treatment with SF $\pm$ polymyxin resulted in significantly increased alveolar air expansion compared to saline- or *E. coli*-exposed animals.

Inoculation of bacteria resulted in severe inflammation of the lungs as confirmed by our histological findings and increased IL-8 levels. The binding property of administered polymyxin cannot reduce the lipopolysaccharide excess originating from Gram-negative bacteria. Thus, the detected IL-8 levels distinguish only between maximum and low inflammation. Inflammation may be attenuated and sepsis may be reduced in experimental pneumonia using different ventilation strategies, e.g. with high positive end-expiratory pressures [12, 13].

Compared to the *E. coli* and SF/PxB groups, a lower degree of pulmonary hemorrhage was found in animals treated with SF only or SF/PxE. This finding is surprising since we did not find any explanations for this in the literature.

In the present study, the addition of PxE or PxB to SF decreased the bacterial load of lungs, which agrees with previous studies on SF/PxB [14]. In a direct comparison, SF/PxE reduces the bacterial load more effectively than SF/PxB. In our study, we used polymyxin sulfate preparations. Sulfation and sulfomethylation may influence antibacterial activity [15] and membrane binding of PxE [16]. PxE sulfate appears to have a higher antibacterial activity compared to PxE (colistin-) methanesulfonate sodium, which presents a prodrug [5, 16].

Thus, the PxE form used in the present study is more active than the form used clinically for inhalation, such as in cystic fibrosis. The high antimicrobial activity correlates to the applied polymyxin concentrations that, in lung homogenates, amount to ~10–20 µg/mL, which is 10- to 20-fold of the minimal inhibitory concentrations of PxE (= 0.25–1 µg/mL) or PxB (= 0.25–2 µg/mL) versus *E. coli* ATCC 25922 [17].

Recently, in vitro studies on bacterial growth found dose-dependent activity of mixtures composed of porcine SF/colistin-methanesulfonate sodium compared to only colistin-methanesulfonate sodium, which is found at low and disappears at higher concentrations of PxE in presence of 1 mg/mL SF ($\geq 64\times$ minimal inhibitory concentration) [18]. Previous studies suggest a reduced PxE activity in the presence of tissue homogenates, lipid extracts, and phospholipids [19], a major constituent of pulmonary SF.

SF as a vehicle for drug delivery is an interesting concept when the pharmacological target is localized in the conducting airways. For antibiotic treatment, this could be during reduced innate or acquired immunity such as during premature birth, mechanical ventilation, chemotherapy, or chronic or acute pulmonary infections. Polymyxins exclusively target Gram-negative bacteria. Liposomal packing of polymyxins has been evaluated for inhalation and for systemic treatment, in order to reduce polymyxin toxicity [20]. Packed in SF, PxE presence in the conducting airways could be extended. At present, the pharmacokinetic parameters of SF/polymyxins such as distribution, half-life, and elimination remain unclear. Further, we do not know whether polymyxins spread along with the SF.

Differences between bacterial translocation to the kidney were found only in the “Px series” but not in the “Px versus PxB series,” in which the kidney was washed additionally. Thus, bacterial load and differences regarding bacterial translocation might no longer be of significance.

The present study confirms that prophylactic intratracheal treatment with SF/PxE reduces pulmonary bacterial load in neonatal rabbit *E. coli* pneumonia. Compared to SF treatment alone, pulmonary compliance is maintained. The model used is suitable for rapid investigation of the early effects on inflammation, lung function, and bacterial load during short-time ventilation. Comparison between treatment with SF/PxB and SF/PxE favors the latter preparation. Further studies are needed to elucidate therapeutic treatment of SF/polymyxin mixtures and the significance of different Px preparations.
