Abstract

Rhabdomyolysis, if severe, can lead to acute kidney injury (AKI). Myoglobin is an iron and oxygen-binding protein that is freely filtered by the glomerulus. Precipitation of myoglobin in the nephrons' distal parts is responsible for tubular damage with AKI as a consequence. Extracorporeal clearance of myoglobin is conventionally attempted by the use of continuous renal replacement therapy (CRRT) with high cut-off dialysis membranes to limit the extent of the damage. We describe a case of a 56-year-old man with traumatic crush injury and a persistent source of muscle ischaemia unresponsive to high dose CRRT with EMI-C-2 filter. Due to therapy failure, he was subsequently treated with the addition of a haemoadsorber (CytoSorb®) to the circuit. This reduced myoglobin and creatine kinase levels successfully despite ongoing tissue ischaemia. However, CytoSorb® was not enough to maintain microcirculatory perfusion, resulting in the eventual demise of the patient due to severity of the injury. Our report indicates that myoglobin was efficiently removed with CytoSorb® following exchange with the conventional high cut-off filter in continuous venovenous haemodialysis in severe traumatic rhabdomyolysis.

Introduction

Rhabdomyolysis is caused by the destruction of striated muscle cells and subsequent release of large quantities of intracellular contents to the circulation, including myoglobin, electrolytes and enzymes [1]. Myoglobin, which is an iron-containing protein weighing 17.8 kDa, is the primary nephrotoxic molecule being released in rhabdomyolysis [2]. Renal tubular obstruction, oxidative injury and vasoconstriction of the renal artery are the proposed mechanisms held responsible for the cause of renal injury [2]. Combined with hypovolemia and metabolic acidosis, myoglobinuria may lead to acute kidney injury (AKI) [3]. More than fivefold increased creatine kinase (CK) levels are generally used as a surrogate for diagnosis of rhabdomyolysis [4–6].

Restricting the damage associated with myoglobinuria is fundamental in treatment [4]. Continuous renal replacement therapy (CRRT) with high cut-off protein permeable filter properties is conventionally used to clear myoglobin from the blood [7].

CytoSorb® (Cytosorbents Corporation, Monmouth Junction, NJ, USA) is a haemoadsorption device capable of removing molecules weighing between 10 and 55 kDa including pro-inflammatory cytokines and myoglobin from the blood. It can be used as part of a CRRT circuit [8, 9].

Inflammatory mediators such as cytokines underline microcirculatory and parenchymal cell damage. Micro-

circulatory alterations are associated with organ failure, such as AKI [10]. They can be observed by sublingual microcirculation using handheld vital microscope.

Here we present a case study of fatal rhabdomyolysis first treated with CRRT and high cut-off filter and later, along with a CytoSorb® adsorber for reasons of therapy failure. The effects of the therapies on sublingual microcirculation are monitored by handheld vital microscopy.

Case Report

This case report describes a 56-year-old male patient, without any previous confirmed medical diagnosis, who suffered severe traumatic rhabdomyolysis of the lower extremities and abdominal wall due to a crush injury.

The patient was rushed to the trauma scene. His hypotension and tachycardia were treated with intravenous fluids. Examination in the Emergency Department revealed a hematoma in the pelvic region and ischaemic lower extremities without any arterial pulse signals. Abdominal computed tomography showed a traumatic dissection of the distal aorta and both arteria iliaca, as well as a bilateral transection of the vena femoralis. Also, laboratory diagnostics showed severe rhabdomyolysis, indicated by myoglobin levels of 79,931 µg/L and CK levels of 15,032 U/L.

The patient was rushed to the Operating Room in an attempt to re-establish arterial supply to the lower extremities. Left arteria femoralis communis and arteria iliaca externa were reconstructed with a synthetic graft. Femoral-femoral crossover construction with a graft from left to right was performed after unsuccessful recanalization of the left iliac artery. Although technically successful, functionality lacked due to persistent ischaemia of >6 h. Lactate was 6 mmol/L. Bilateral guillotine amputation above the patella was performed.

The patient was postoperatively transferred to the intensive care unit (ICU), and treated with mechanical ventilation and ad-

ministration of high-dose noradrenaline ranging between 0.6 and 0.8 µg/kg/min. Broad-spectrum antibiotics were initiated. CRRT with Continuous Veno-Venous Hemo-Dialysis mode was initiated with a high-cut off EMIC-2 dialysis filter (Fresenius Medical Care, Bad Homburg, Germany) to remove excess myoglobin from the bloodstream. The settings were as the following: Blood flow rate: 200 mL/min, Dialysate flow rate: 4,000 mL/h, Prescribed Renal Dose: 50 mL/kg/h (patient weight: 80 kg). No anticoagulation was employed due to severe shock and deranged coagulation parameters (international normalized ratio >10 and activated partial thromboplastin time >180 s). Evolution of the kidney functions and myoglobin and CK levels can be seen in Figures 1 and 2 during this phase.

The fluid balance for the first day was +14,000 mL, and average noradrenaline demand was 1 µg/kg/min. To guide fluid and vaso-active drug therapy, continuous cardiac output monitoring by use of transpulmonary thermodilution (PiCCO®) device was applied. Six packs of red blood cells were transfused. Sublingual microcirculation measurement showed a rich and mostly perfused vessel density, which was analyzed by dedicated software [11]: total vessel density (TVD): 22.73 mm/mm², percentage of perfused vessels (PPV): 0.93 (online suppl. Video 1; for all online suppl. material, see www.karger.com/doi/10.1159/000505899). As the patients' status did not improve, and neither myoglobin nor potassium levels could not be lowered, a re-exploration surgery was performed, and the vitality of the tissues was assessed. A subsequent laparotomy revealed sigmoid ischaemia, and in response, a proctosigmoidectomy was executed.

Despite the literature [5, 7], the EMIC-2 filter alone was not able to prevent progressive myoglobin increase following this procedure. In response, a CytoSorb® adsorber was added to the circuit instead, as shown in [12], on the second day of the ICU stay. Myoglobin levels were lowered significantly from 110,000 to 90,000 µg/L as well as CK levels from 115,000 to 65,000 U/L within 4 h of CytoSorb® treatment. Rapid saturation of the adsorber was noticed necessitating a change of adsorber after 12 h of initiation. After CytoSorb® replacement, levels again were reduced from 110,000 to

Fig. 2. Evolution over time of creatinine and urea levels during CRRT with EMIC-2 and CRRT with EMIC-2 plus CytoSorb in series.

70,000 µg/L within 12 h. However, noradrenaline consumption could not be lowered, ranging between 1.15 and 1.25 µg/kg/min. The fluid balance was +9,900 mL. This inquired another re-exploration revealing rectum stump ischaemia. Three packs of red blood cells were transfused. Sublingual microcirculation measurement was similar to day 1 with a TVD of 23.53 mm/mm² and PPV of 0.99.

The patients' condition deteriorated further on day 3. Noradrenaline consumption hit the highest level of 1.75 µg/kg/min and could only be lowered to a minimum of 1.15 µg/kg/min with the help of a renewed CytoSorb® adsorber. Enoximone 1 µg/kg/min and Amiodarone 600 mg over 24 h were initiated to no avail. Another laparotomy showed total avital rectus abdominis muscles. No further treatment was possible. Despite this unresolved source, myoglobin levels were reduced from 90,000 to 50,000 µg/L and CK 65,000 to 40,000 U/L. Sublingual microcirculation ceased to flow hours before patients final demise: TVD: 12.46 mm/mm² PPV: 0.06 (online suppl. Video 2). Parallel to this, lactate levels did not normalize. Haemodynamic parameters and blood values associated with the case are shown in Table 1.

Discussion

Severe rhabdomyolysis often results in myoglobinuria and AKI. High volume CRRT with high cut-off protein filters can be employed to restrict ensuing damage, although this only affects myoglobin levels and not CK. Despite the application of a high cut-off EMiC-2 dialysis filter with a high blood and dialysate rate, myoglobin levels were not reduced significantly, and CK levels increased massively. Blood purification with haemoadsorption has been shown to filter non-specifically pro-inflammatory molecules from the bloodstream. Also, myoglobin has

been shown to be filtered in an animal model of smoke and burns injury [13].

Our report shows that the use of CytoSorb® in this severe rhabdomyolysis patient was successful in reducing plasma concentrations of myoglobin and CK despite an unresolved source of bowel ischaemia and unnoticed abdominal wall ischaemia. Furthermore, the CytoSorb® adsorber was shown to be more successful at eliminating myoglobin and CK than conventional EMiC-2 filter. An adsorber change per 12 h or even earlier seems plausible in severe cases to ensure continuous mediator reduction.

One could argue that, the demise of the patient could have been the consequence of severe shock which could not be fully resuscitated as indicated by the low cardiac index and high lactate levels. Normalization of the macrohaemodynamic indices was attempted by use of fluids, vasopressors and vasoactive agents in our patient. The high lactate levels despite the resuscitation can be both due to unresolved source and/or flow heterogeneity with oxygen extraction deficit that is seen in patients with septic shock [14]. Although, hyperlactatemia is valuable in the initial phases of shock, haemodynamic coherence rapidly disappears over hours and limits lactate usage in prolonged shock [15]. Additionally, we did not detect any flow heterogeneity in the sublingual microcirculation measurement of the patient in the first 2 days of the ICU stay. It is our interpretation that in this initial phase of systemic haemodynamic compromise, regulatory mechanisms at the regional level were still able to keep the mi-

Table 1. Hemodynamic and blood values

crocirculation perfused. However, following persistent depressed macrocirculation, the microcirculation could no longer be sustained and the alterations we observed set in, followed by the unfortunate death of our patient.

Additionally, our report shows that myoglobin can significantly affect not only the renal perfusion but also systemic tissue perfusion, but the outcomes of this effect may take time to develop. Myoglobin has a considerably lower oxygen half saturation (p50) compared to haemoglobin (2.8 vs. 26 mm Hg) and impairs tissue oxygenation by strongly binding to oxygen [16]. Myoglobin also increases vascular resistance, impeding perfusion further [17]. Thus, excess myoglobin can affect 2 determinants of microcirculatory and tissue perfusion, that is, convection and diffusion of oxygen. Persistence in such a condition as in our case, led to the eventual deterioration of the microcirculation too, suggesting that the timing of CytoSorb® application may have been critical and that in such conditions early application of CytoSorb® may be indicated to avoid the progression from normal to abnormal microcirculation.

Lastly, there was a discrepancy in the trends of urea and creatinine levels during CRRT. CRRT was successful in reducing the urea concentration but not the creatinine. Previous studies reported a parallel reduction in both [18–20]. This may have been on account of ongoing muscle destruction.

In summary, this study shows that the haemoadsorption with the CytoSorb® adsorber improves both myoglobin and CK clearance compared to the initial high dose

CRRT with EMI-C-2 filter. Treatment with CytoSorb® improved the microcirculatory perfusion at day 2 of the ICU stay, despite abnormal macrohaemodynamic parameters showing a loss of haemodynamic coherence. However, injuries were so severe that just the removal of myoglobin and CK did not result in survival at day 3. This report underscores our opinion the need to install the adsorber in an early phase for removal of inflammatory cytokines and myoglobin.

Statement of Ethics

Written informed consent to publish the case report was taken from the nearest kin available. The study was conducted according to the principles of the Declaration of Helsinki (version 2013, October; www.wma.net) in accordance with laws and medical research involving humans (WMO) and the requirements of Dutch law regarding human-based research.

Disclosure Statement

C.I. has received a grant from CytoSorb to commence a randomized controlled trial on the effect of the adsorber on the microcirculation of critically ill patients at the department of Intensive Care of the Erasmus Medical Center Rotterdam. C.I. and his team provide services and training with regard to clinical microcirculation. To this purpose, he runs an internet site called <https://www.microcirculationacademy.org>. The internet site and its activities are run by a company called Active Medical BV of which he owns

shares. O.D. received a research grant from the Scientific and Technological Research Council of Turkey (TUBITAK grant no: 1059B191800363). Other authors declare no conflicts of interest.
