Short title: Evaluation of renal function status in children with sickle cell disease
Key words: Sickle Cell Anaemia•Renal Function•Urine Albumin Creatinine Ratio•Human Neutrophil Gelatinase-Associated Lipocalin

Highlights of the Study
- Renal function status of the children was assessed using urine albumin creatinine ratio and urine human neutrophil gelatinase-associated lipocalin
- This study shows that kidney injury possibly begins early in childhood in sickle cell individuals and that albumin creatinine ratio is more sensitive than urine human neutrophil gelatinase-associated lipocalin in assessing renal injury in this age group.
- Findings of this study further emphasize the importance of periodic renal evaluations in sickle cell children, for early identification of those at risk of kidney injury.
Abstract

**Introduction:** Sickle cell anaemia is characterized by defective haemoglobin synthesis and is associated with both endocrine and metabolic alterations. The effects of this clinical condition on kidney function are multi-factorial and often begin early in childhood. This study aims to assess renal function in children with sickle cell anaemia using urine albumin:creatinine ratio (ACR) and urine human Neutrophil Gelatinase-associated Lipocalin (NGAL).

**Methods:** This case-control study was conducted on 200 children aged 5 to 15 years in two tertiary hospitals in South West Nigeria; 150 were of haemoglobin S genotype and 50 were of haemoglobin A genotype. Serum urea, creatinine, urine albumin, creatinine and NGAL were assayed by known standard methods. eGFR, urine ACR and urine NGAL/creatinine ratio (urine NCR) were calculated. **Results:** The weight, height, BMI, systolic blood pressure (SBP), plasma urea, plasma creatinine and spot urine creatinine of the HbS genotype children were significantly lower compared to that of the HbA genotype children. The eGFR, spot urine albumin and urine ACR was significantly higher in the HbS group compared to the HbA group. There was no significant difference in the spot urine NGAL and urine NCR between the two groups, though both were higher in the HbS group compared to the HbA group. **Conclusions:** Kidney injury probably starts early in childhood in sickle cell individuals as indicated by the higher urine ACR detected in them. We infer that urine NGAL and uNCR are not sensitive markers of kidney disease especially in young sickle cell individuals possibly because of the hyperfiltration present at this age.

Introduction

Sickle cell disease (SCD) is an autosomal recessive disorder resulting from mutation in the β-globin gene of haemoglobin, leading to production of an unstable isoform, haemoglobin S(HbS) which when deoxygenated can polymerize causing sickling of the red blood cell, vaso-occlusion, and haemolysis. Sickle cell disease includes sickle cell anaemia (SCA) which is due to homozygous inheritance of hemoglobin S (HbSS), consequently the most severe form of SCD. The prevalence of the sickle cell trait in many tropical African countries including Nigeria ranges between 20 and 30% of the population [1].

Sickle cell nephropathy is a common and serious complication of SCA that begins in childhood and may progress to overt renal failure. Structural and functional changes may occur in the kidney as a result of the haemodynamic changes associated with chronic anaemia and renal hypoxia resulting from the recurrent vaso-occlusion and haemolysis-related endothelial dysfunction. These changes present as concentrating defect, renal insufficiency, haematuria, proteinuria and hypertension which eventually progress to chronic kidney disease (CKD) [2]. Chronic renal failure has been increasingly diagnosed in HbS patients and, in some countries, it is one of the most common causes of death among HbS patients over 40 years of age. The prevalence of renal failure in sickle cell disease ranges from 5 to 18% [3]. Studies have shown that preventive strategies can significantly reduce the burden of renal diseases [4, 5] hence the importance of detecting kidney injury at early age especially in children with haemoglobin S genotype.

There are several available serum and urine biomarkers of renal injury including urea, creatinine, urine albumin and urine human Neutrophil gelatinase-associated lipocalin, but none of them could accurately predict the outcome of the disease at the initial stages. Kidney diseases can be diagnosed on the basis of serum creatinine concentration and estimated GFR, albuminuria, renal imaging, and histology following renal biopsy [6]. The plasma urea and creatinine are the commonest and generally recognized parameters utilized in the assessment of renal functions, such that their elevated concentration is a pointer to impaired renal function. A number of extra-renal factors affect the plasma concentrations of urea and creatinine so limiting their significance as a test of kidney injury, therefore should not be used alone [7]. Plasma creatinine is used in the estimation of glomerular filtration rate which is the optimal way to assess kidney function and in conjunction with albuminuria can help determine the extent of CKD in an individual.

Glomerular filtration rate is measured using plasma or urinary clearance of an exogenous filtration marker such as inulin, however it is a complex procedure and generally not routinely performed; therefore, GFR is usually estimated from an individual’s plasma creatinine concentration in combination with demographic factors such as age, race, and gender using various formulae [8]. A decrease in GFR precedes onset of kidney failure such that persistently reduced GFR is a specific diagnostic criterion for CKD. One of the major manifestations of renal injury observed in children with sickle cell anaemia is glomerular impairment characterized by an early increase in
glomerular filtration rate (GFR) associated with high- or overt albuminuria, followed by a gradual decline of GFR and finally chronic kidney disease [9]. Albuminuria, an increase in urinary excretion of albumin, is also a sensitive marker of glomerular damage that may indicate early chronic kidney disease and its considered to be a relevant biomarker of early glomerular damage in patients with sickle cell disease. A routine dipstick is not sensitive enough to detect small amounts of urinary protein (albumin), therefore to evaluate albuminuria it is recommended to measure urine albumin-to-creatinine ratio (uACR) in a spot urine sample; because urine albumin varies greatly throughout the day whilecreatinine is excreted in a relatively steady rate. Although the 24-hour urine collection is the "gold standard," to quantify urinary protein, ACR in spot urine specimen correlates well with 24-hour urine collections and it is less cumbersome. It has been shown that in sickle cell individuals, a prolonged period of high-albuminuria precedes gross persistent proteinuria, followed by renal failure as age increases [10]. Rapid rise in levels of urine NGAL compared to levels of serum creatinine in response to AKI is one of its benefits over creatinine and contrary to these conventional markers, NGAL is not considered a marker of renal function, but a reflection of structural damage of renal cells. NGAL therefore shows a progression of the early renal structural damage occurring during kidney disease despite normal GFR [11]. It is proposed that uNGAL estimation should be done along with urine creatinine measurements and uNGAL/creatinine ratio (uNCR) calculated, this is due to high biological variability of urinary NGAL (uNGAL), especially in CKD [12]. It has been reported that there is a positive association between uNGAL, albuminuria and kidney disease progression; and a negative correlation between uNGAL, uNCR and eGFR, irrespective of the level of albuminuria [13]. Additionally, uNGAL seems to be a better biomarker in children and adolescents as its assessment is less invasive than assessing even serum Cystatin C level and that it can be measured using a single urine sample [14]. The interpretation of the result, however, is often difficult in paediatric population because of lack of age- and sex-specific normative values. Previous published urine NGAL values, ranged from 1.64 (0.25–5.77) ng/mL in healthy children [15] to 5 (2–150) ng/mL in very low birth weight infants [16].

There are only few publications regarding kidney injury in paediatric patients with sickle cell disease and information on the renal status of children with haemoglobin S genotype in Nigeria is sparse and conflicting, thus the need for this present study. Early detection of HbS genotype children who are at a high risk of kidney impairment is highly significant as it helps to apply measures which can delay progressive kidney dysfunction. This present study therefore compared the renal function using eGFR, urine ACR, urine NGAL and urinary NCR in HbS and apparently healthy HbA children, as a means to assess the effect of sickle cell anaemia on the renal indices at early childhood.

Methods

Study Participants

This is a case-control study carried out among 200 children aged between 5 and 15 years in two tertiary hospitals from South West, Nigeria over a period of 6 months (April-November 2019). 150 were HbS genotype and 50 were HbA genotype. The study participants were selected from children attending the paediatric haematology clinic after satisfying the inclusion criteria using a non-random sampling technique. The study was approved by the Olabisi Onabanjo University Teaching Hospital Health Research and Ethics Committee (OOUTH/HREC/257/2019).

Data Collection

A questionnaire-based interview was used to collect information on demographic characteristics, clinical measurements. Informed written consent was obtained from all participants guardians after educating them on the benefits and relevance of the study. Clinical measurements which included weight (Kg), height (meters) were measured with participants in light clothing without shoes using a stadiometer and the stadiometer’s head piece, respectively. Body Mass Index was calculated as Weight/ Height2 (kg/m²). Blood pressure was measured twice (10 minutes apart), on the left arm of participants in a relaxed, sitting position with the arm supported at heart level, using a standard mercury sphygmomanometer. The mean of the two readings was calculated to obtain the final blood pressure.

5ml of venous blood was withdrawn from each participant and dispensed into Lithium heparin sample bottle for plasma urea and creatinine estimation, while 10mls of spot urine specimen was collected for urine albumin, urine creatinine and human Neutrophil Gelatinase-associated Lipocalin (NGAL) estimation. The lithium heparin specimen bottles were centrifuged at 3000g for 15 minutes using Uniscope Laboratory centrifuge, model SM 112 (Surgifriend Medicals, England) and plasma decanted into respective well labeled plain bottles. Respective plasma and urine samples were stored at -20°C using the freezer compartment of the SCANFROST model SFVFFF 350 until analysis within a period of 3 months.
**Assay Methods**

Serum urea was measured by Urease-Berthelot colorimetric method, serum and urine creatinine were quantified using alkaline picrate colorimetric method, urine albumin was quantified using immunoturbidimetric assay while urine human Neutrophil Gelatinase-associated Lipocalin (NGAL) was measured by ELISA method. eGFR was calculated using the Revised Bedside Schwartz Formula. Urine Albumin/creatinine (uACR) and urine NGAL/creatinine (uNCR) ratios were also calculated.

**Statistical Analysis**

Statistical analysis was done using the IBM statistical package for social scientist (SPSS) version 23.0. The data are expressed as mean ± standard error. The Student’s t-test was used for comparisons of means while Pearson’s correlation was done to find associations between eGFR and plasma urea, creatinine, urine ACR, urine NGAL, urine NGAL:creatinine ratio. P values < 0.05 were considered significant.

**Discussion**

In this present study the homozygous sickle cell disease children were of shorter stature when compared with their age-matched control (HbA genotype children) as shown in “Table 1”, this is similar to reports by Nogueira et al, 2015 and Al-Saqladi et al, 2008 [17, 18]. Thus, in agreement with the previous studies, this present study shows that sickle cell anaemic children are growth deficient compared to children with HbA. We observed that children with HbS have lower plasma urea and plasma creatinine compared to HbA controls as shown in “Table 2”; this is similar to previous reports by Aloni et al 2014 and Aleem et al 2008 [19, 20]. Also in agreement with previous reports submitted by Aleem et al 2008 and Aygun et al 2011 [20, 21] that elevated GFR is predominant in sickle cell paediatric series, the eGFR in this present study is higher in HbS children compared to HbA children “as shown in Table 2”; though both are in the normal GFR category for CKD staging. This elevated eGFR referred to as hyperfiltration is common in young patients suffering from sickle cell disease due to glomerular hypertrophy such that in poor resource settings, hyperfiltration is a major indicator of deterioration in renal function, which occurs earlier than decreased creatinine clearance and/or proteinuria [22]. The amount of creatinine produced in the body each day is relatively constant and it is related to the muscle mass; this coupled with the glomerular hyperfiltration might explain the lower concentrations of creatinine and urea in HbS who are of smaller stature compared to their HbA counterpart.

This study showed that urine albumin and urine albumin creatinine ratio of the sickle cell children are significantly higher than those of HbA counterpart “as shown in Table 2”, this is similar to previous findings by Ranque et al 2014 [23]. There is also moderately increased albuminuria in the sickle cell anaemic participants indicating stage A2 CKD albuminuria category, while the HbA participants are in the normal albuminuria category. It is known that albuminuria is a sensitive marker of glomerular damage; therefore it can be inferred from this study that the sickle cell anaemic children may be in the early phase of kidney damage with compensatory increase in glomerular filtration which may be responsible for the enhanced glomerular passage of albumin.

It is imperative to note that serum creatinine and its derived estimated glomerular filtration rate (eGFR) might be of limited diagnostic value in detecting early renal dysfunction due to many factors that affect the generation and excretion of creatinine. It has also been reported that not all individuals with conditions such as diabetic nephropathy have increased albuminuria, therefore a search for new markers for kidney damage seems necessary.

Neutrophil gelatinase-associated lipocalin (NGAL) and kidney injury molecule-1 (KIM-1) are released by injured tubular epithelium cells, and interleukin-18 (IL-18) is an inflammatory mediator released during AKI. These molecules, which take part in the early pathophysiological changes in AKI, have been recently evaluated as potential new biomarkers. Tissue inhibitor of metalloproteinase-2 (TIMP-2) and insulin-like growth factor binding protein-7 (IGFBP7) both act to block the G1 stage of the renal tubular epithelial cell cycle during AKI [24]. With varying degrees of accuracy, these markers all provide information about the state of the kidney much earlier than do changes in function (i.e., serum creatinine).

Neutrophil gelatinase-associated lipocalin (NGAL), a member of the lipocalin protein family, has been identified as one of the most useful biomarkers to detect kidney disease in its early stages. Available reports focus mainly on the role of NGAL as a biomarker of acute kidney injury (AKI) but it is worthy of note that it may also serve as a marker of chronic kidney disease, especially diabetic nephropathy [25].

There is a paucity of reports on urine NGAL in sickle cell children especially in Nigeria and this present study might be among the very few to investigate renal status in this group of children using urineNGAL. In this present study the urine NGAL and urine NGAL:creatinine ratio is higher in HbS participants compared to HbA controls “as
shown in Table 2”, though not significantly different, this is similar to the findings of Woo et al, 2012 [26] and Atere et al 2018[11]. Atere et al looked at NGAL as a marker for acute kidney injury among sickle cell subjects (both steady state and vaso-occlusive crisis state) aged 18-60 years and reported significantly higher NGAL in them compared to controls while Woo et al reported significantly higher urinary NGAL levels in diabetic CKD patients than in healthy controls. The participants of this present study are children, aged 5-15 years with no AKI or CKD; this might explain the lack of significant difference in the measured urine NGAL or calculated urine NCR as compared to studies by Woo et al and Atere et al where adult patients with known AKI or CKD are compared with apparently healthy controls. Research has shown that in patients with chronic kidney disease, elevated urine NGAL is a good predictor of CKD progression [27] and urine NGAL been a marker of structural damage of renal cells, then it can be proposed from this present study that some level of structural kidney injury though insignificant, might be present in sickle cell individuals from childhood which might progress to AKI and CKD as they grow older.

The current study shows a strong negative correlation between the eGFR and the plasma creatinine of sickle cell children as shown in “Table 3”, this is similar to the finding of Srivastava et al 2011 [28] in which it is reported that serum creatinine increases in renal failure correlating with a decrease in GFR forming a curvilinear relationship. These findings efficiently demonstrated that decline in glomerular filtration is associated with rise in plasma creatinine concentrations.

We did not observe any correlation between the eGFR, measured urine NGAL and calculated urine NCR shown in “Table 3” as compared to the findings of Woo et al and Atere et al in which urinary NGAL level showed a significant inverse correlation with eGFR in the studied participants. Atere et al reported that NGAL correlates positively with the duration of sickle cell disease mainly when eGFR is decreased, this might also explain the lack of correlation in this present study where participants are children with hyperfiltration; therefore NGAL might not be a sensitive marker of kidney disease in sickle cell children probably in the absence of AKI or CKD.

Conclusions
Kidney injury possibly begins early in childhood in sickle cell individuals as indicated by the moderately but significantly increased albuminuria found in them. It is likely that urine NGAL and uNCR might not be a sensitive marker of kidney disease in sickle cell individuals especially when they are young possibly because of the hyperfiltration present at this phase of their life. Limitations of this study include its small sample size and the use of a single marker of structural kidney injury. However, findings of this study buttressed the known fact that it is crucial to perform periodic renal evaluations in sickle cell children, so as to detect early those at risk of kidney injury and apply measures which can delay progressive kidney impairment.

Statements
Acknowledgements
We are thankful to the study participants for making this study possible. We also acknowledged the help of the entire Department of Paediatric Haematology unit of both Olabisi Onabanjo University Teaching Hospital and Federal Medical centre, Abeokuta for their assistance.

Statement of Ethics
All procedures performed in this study involving human participants were in accordance with the ethical standards of the Olabisi Onabanjo University Teaching Hospital Health Research and Ethics Committee ‘Reference number OOUTH/HREC/257/2019’ and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.
