Abstract

In recent years formal methods from concurrency theory and process calculi have gained increasing importance in modelling complex biological systems. In this paper propensity to biological interaction, as seen by the shape spaces theory, is given a linguistic interpretation. Entities from the living matter are viewed as terms of a formal concurrent language of processes with typed interaction sites. The types are strings, and interaction depends on their distance. Further, the language is associated with syntax-driven rules that permit the inference of the possible computational behaviours of the specified biological system. This approach leads to the use of all the methods and techniques developed in the context of formal languages (e.g., language translation, model checking), opening new ways of studying complex biological systems.

Prandi, Priami, and Quaglia extol the virtues of a linguistic interpretation of formal methods from concurrency theory and process calculi that have recently gained increasing importance in modelling complex biological systems. Specifically, they consider how shape spaces theory can improve our understanding of biological interactions. Within this framework living entities are seen as the terms, or words, of a language and their interactions become the grammar and syntax of this language. Such an approach, they explain, allows us to infer putative behaviour in a biological system – an ecosystem or a whole organism for instance – by applying the rules of formal languages, such as language translation and model checking, to this biological prose.

The various genome projects were only ever to be the beginning of our quest to understand life. They provide a starting point from which to expand our knowledge of living things, such expansion means we must now face a scaling up of the size of the scientific problems to be solved. Prandi, Priami, and Quaglia point out that the rapid growth of experimental data is not yet underpinned by a corresponding improvement in the analytical tools for investigating biological systems. Scientists would hope to model and control biological processes, but their complexity is only revealed as more profound by the burgeoning experimental data set. Complexity, of course, does not lie in the static data itself but in the countless interactions of the constituents of any given system and the consequent behaviour that emerges. Complexity is related directly to these interactions, and as such a classical reductionist perspective is unlikely to provide any genuinely useful insights. An alternative approach is needed.

We need an integrated or systemic view of the investigated phenomena that is hypothesis driven and based on formal/mathematical grounds, explain the re-

1 Introduction

In the next century biology research will be strongly influenced by the way in which we will be able to address the complexity of systems. After the Human Genome Project we have to face a scaling up of the size of problems. Unfortunately this fast growth in knowledge is not supported by a corresponding enhancement of the methods and techniques for analyzing biological systems. The complexity of the processes we want to model and control is mainly given by the interactions of the constituents of the systems and the consequently emergent behaviours. Therefore, the complexity of a biological system is related to the interconnected nature of the problem under analysis. In this context, the classical *reductionist* approach seems no more suitable to handle the current challenges. We need an integrated or systemic view of the investigated phenomena that is hypothesis driven and based on formal/mathematical grounds.

Following these principles biology is moving to the so-called *systems biology*. Systems biology is an approach based on systems theory in the applicative domain of biological processes. The basic idea is to view each system as something that has its own behaviour not obtained simply by gluing the behaviour of the systems components, of which we already have all the information. We could say that biology is moving towards the organization of the knowledge acquired with the Human Genome Project and with the high-throughput tools.

The challenge we are now facing is to model, analyze and possibly predict the temporal and space evolution of complex biological systems. The key point seems to be to find a suitable level of *abstraction* to model the phenomena of interest. In this respect we need to build a framework that allows us to speed up the understanding of the systems in hand and to exploit the knowledge we are going to discover. Computer science proposed many abstractions

to model behaviour and evolution of complex systems over the last decades. We could now adapt such abstraction to the new applicative domains such as, e.g., molecular biology or immunology. The basic techniques we should exploit with this strategy are completely different from those used so far in bioinformatics because they lie in the programming languages and modelling field rather than in the classical algorithmic one.

Systems biology should not be seen as a 'revolution' but rather as a *change* of paradigm. Over the years biologists have understood that they need models for representing and understanding complex biological phenomena. For instance, the widely accepted Gillespie's algorithm [1] is a stochastic model that describes the temporal evolution of biochemical reaction. The programming language approach allows the integration and organization of different models in a unique picture. Biochemical stochastic π -calculus [2] integrates Gillespie's algorithm in a programming language leading to the use of computer science theory for analyzing biochemical reactions. In this paper we make a step further in this direction enriching beta-binders [3], a language for describing molecular interactions, with the shape space model [4], a model for representing protein shapes.

The rest of the paper is organized as follows. Section 2 presents process calculi in the context of systems biology. In this section we outline a limit of process calculi for systems biology and we see how shape spaces can be used for overcoming this limit. Section 3 introduces the shape spaces theory. Next, in section 4, the beta-binder language is briefly recalled. For complete formal details, the interested reader is referred to Priami and Quaglia [3]. Here we stick to a graphical and intuitive presentation, and focus on those modifications that allow shape spaces to be natively dealt with in the language. Section 5 concludes the paper with an application of the

searchers. In this context, systems biology becomes the inevitable starting point. This is based on the underlying principle that the behaviour of each system is inherent and is not simply obtained by tacking together the behaviour of its component parts. Finding a suitable level of abstraction to allow us to exploit this new paradigm is the key. Computer scientists have, over the last few decades, developed many abstractions to model behaviour and the evolution of complex systems. Biologists, suggest Prandi, Priami, and Quaglia, could adopt one such abstraction and apply it to the domains of molecular biology or immunology, for instance. Adopting this attitude would be in sharp contrast to the techniques used in bioinformatics to date, because they would exploit computer programming languages and the modelling field rather than classical algorithms. A programming language approach will allow us to integrate and organize different models to create a unique picture and hopefully profound new insights.

A stochastic model, such as Gillespie's algorithm for describing biochemical reactions, acts as a starting point as it can be hybridized with a programming language. Prandi, Priami, and Quaglia then hope to take this a step further by enriching beta-binders, a language for describing molecular interactions, with the shape space model, a model for representing protein shapes.

Process calculi, by definition, are formal languages that were developed to model distributed systems. Basic parallel components interact either as standalone machines or through data transfer. The language will have a limited number of operators to describe the interactions and behaviour of the components. It then follows that the syntax of the language provides a picture of what processes and changes might take place with interactions being seen as a key-lock metaphor. Regev and Shapiro suggested that distributed systems and living matter are analogous, so that process calculi might be used to

language to a simple example inspired by the immune system. We show how the phenomenon can be modelled and comment on the behaviour that can be derived by applying the rules of the language. Finally section 6 concludes the paper and proposes some perspectives.

2 Process Calculi in Systems Biology

Process calculi are formal languages that have been originally developed for modelling distributed systems. They typically make possible the abstract description of complex interacting entities in terms of basic parallel components that can either act as stand-alone machines or synchronize and exchange data. Once a language with a limited number of operators is fixed, the specification of a system (synonym of *process*) is given as a term that fully defines the way in which the various parts of the system are put together. They may be sequentialized (meaning that the operations of one component have to be performed before those of another one), let run in parallel, repeated many times, etc. The formal language, and hence its sentences, is further associated with syntax-driven rules that permit the inference of the possible computational behaviours of the specified system. Those rules, which can be implemented by an automated tool, allow, e.g., to state that a given process $\mathcal{P}$ transforms into the process $\mathcal{Q}$, written $\mathcal{P} \rightarrow \mathcal{Q}$.

A recent research paper by Regev and Shapiro [5] points out the analogies be-

tween distributed systems and the living matter. Indeed, various description languages in the style of process calculi have already been proposed to model biological behaviours [see, e.g., 2, 6–8]. These languages allow the automatic simulation of all the possible future behaviours of the modelled molecular system, as well as the use of the methods for qualitative and quantitative analysis developed for classical process calculi. The challenge is to thoroughly investigate the relation between biological knowledge and process calculi representation for finding the ‘best’ abstraction. Within this paper we make a step further in this direction by grounding process calculi in a well-developed biological model.

Classical process calculi assume a *key-lock* model for interactions (think, e.g., of the strict matching between an input and an output over a given channel). Under this assumption only the interaction (a) in figure 1 is possible, while (b) is not. This is because ‘interfaces’ of the components 1 and 2 match exactly, while those of 1 and 3 do not. Reactions like the one drawn in (b), however, are quite common in biology [9].

A proposal to relax the key-lock assumption is beta-binders [3]. In this formalism, processes are encapsulated into boxes with interfaces that are identified by a name and have an associated *type* that represents the interaction capabilities of the box. A type is a set of names, and the interaction is made possible if and only if the types of the interfaces of the two part-

model biological. Prandi, Priami, and Quaglia then explain that the challenge is to investigate the relation between biological knowledge and a representation created using process calculi to find the optimum form of abstraction.

The researchers have now taken a step towards this goal in the present paper by relaxing the notion of key-lock interactions between entities being essential. The beta-binders language side-steps the key-lock notion by introducing the concept of ‘affinity’. Rather than fixed key-lock interactions, affinity is grounded in shape spaces, a mathematical model introduced by Alan Perelson and George Oster for modelling molecular ligand in the immune system. The model is generalized for modelling protein interactions.

Proteins are composed of different independent structural parts called domains. How these interact depends on the structural and chemical complementarity of particular portions, called molecular determinants or motifs. By describing them using geometric quantities which specify the size and the shape of the molecular determinant, and physical characteristics of the protein’s constituent amino acids, such as charge or the ability to form hydrogen bonds, a vector space, called shape space, can be defined. Therefore, a protein is represented as a point in this shape space and the distance between two points can then be used as a measure of the tendency of two molecular determinants to interact. Of course, it is computationally intensive to carry out calculations in an N-dimensional shape space so the notion of shape can be collapsed to strings instead. This brings with it the advantage that carrying out these strings are themselves analogous to the protein’s amino acid sequence. Computational efficiency, explains the team, is gained by relying on strings and string matching rules to represent the affinity of motifs.

Finding appropriate string matching rules for particular biological situations is

Fig. 1. Interaction models.

ners are not disjoint. For example x : Δ and y : Γ are two beta-binders. The first interface has the name x and type Δ and the second one has the name y and type Γ . The interaction is allowed if and only if $\Delta \cup \Gamma$ is not empty. This model might be too abstract for practical biological use, and indeed it was originally chosen by the authors just as a very simple form of typing policy for processes interacting through names. Therefore, we introduce here a notion of *affinity* that is finer than the one expressed by the intersection of the types of interfaces. We formally ground the concept of affinity on *shape spaces* [4], a model introduced in the context of immunology, and we incorporate them into beta-binders.

3 Shape Spaces

Shape spaces [4] were introduced in the context of the theoretical studies of clonal selection in the field of immunology. In this section we generalize the ideas underlying this methodology abstracting as many biological details as possible.

A protein is composed of many different independent structural parts called *domains*. The interaction capability between domains depends on the structural and chemical complementarity of particular portions, called *molecular determinants* or *motifs*. Suppose it is possible to describe the features of a motif by specifying N 'shape' parameters. These parameters include geometric quantities which specify the size and the shape of the molecular determinant, and physical characteristics of amino acids comprising the motif (e.g., the charge or the ability to form hydrogen bonds). The N parameters define an N -dimensional vector space that is called *shape space*, say S . A point in S represents a molecular determinant. A function $C: S \rightarrow S$ maps motif shapes to their complements. By defining a metric on S , the distance between two points can be used as a measure of interaction propensity between two molecular determinants.

The above intuitions are shown in figure 2. We assume that two parameters N_1 and N_2 suffice to describe molecular determinants, leading to a 2-dimensional shape space. Moreover we choose the Euclidean metric, obtaining an Euclidean shape space [10].

As an example, let us consider two proteins A and B , with molecular determinants M_A and M_B , respectively. The molecular determinants M_A and M_B are two points in the 2-dimensional Euclidean shape space. The function $C: N_1 \times N_2 \rightarrow N_1 \times N_2$ maps M_B into its complement $C(M_B)$, and the distance $\varepsilon = \|M_A - C(M_B)\|$ represents the molecular affinity between the motifs M_A and M_B . In order to get symmetric interaction propensity, one can require $\varepsilon = \|M_A - C(M_B)\| = \|C(M_A) - M_B\|$.

If the N shape parameters do not contribute equally to the specificity of a motif (e.g., small charge differences could be more important than small differences in geometry), a metric different from the Euclidean one is necessary. Finding an appropriate metric for measuring the affinity of molecular determinants is a nontrivial task in chemistry. The specific choice of the metric, however, does not affect our semantics.

It is computationally difficult to calculate a distance in a high-dimensional continuous space. For this reason the abstract model of the shape spaces is not particularly well suited to a concrete implementa-

Fig. 2. Shape space example.

the next obstacle to be overcome. There are several distinct rules in the literature, such as the Hamming distance and the Manhattan distance. The first is given by the number of positions in which two strings differ, while the Manhattan distance between two strings is the sum of the distances between their digits. Then there is the XOR rule in which each symbol in the string is represented as a binary number, and the distance between two strings is computed as the normalized sum of the digits of the XOR of the two numbers. XOR has several advantages over both the Hamming and Manhattan. However, the strings are assessed, the bottom line is that the shorter the distance, the greater the tendency to interact of the two biological entities.

Having thus defined their framework, Prandi, Priami, and Quaglia then invoke the beta-binders formalism. This language builds on the intuitive notion that biological entities have an internal 'processing unit' and an 'interface' that they present to the external environment. Thus, a protein has a backbone and motifs for interacting with its environment, similarly a cell has a membrane whose proteins act as an interface, and a complex internal structure that responds to the external changes. Within the context of immunology, such an interpretation of the cell is useful where one considers cell populations rather than individual cells. Beta-binders then discriminate between allowed and disallowed interactions with the environment and can be set up to reflect real biological situations, for example, internal modifications of the structure of a protein that compete with environmental solicitations, for instance enzyme activity.

By bringing these various threads together the team could produce a simple model of the immune system focusing on a few key players. As example, they considered a small system composed of a cell, a virus, and a cytotoxic T cell. First, they represent the three actors as boxes with appropriate binders using beta-binders. Then

tion. Computational efficiency is gained by relying on strings and string-matching rules to represent the affinity of motifs. Each motif is associated with a string of symbols, and hence a string can be loosely interpreted as an amino acid sequence. Different symbols represent different values of properties of the amino acids, like, e.g., hydrophobicity or charge.

To effectively compute the interaction propensity between motifs it is necessary to define a string-matching rule. Choosing the ‘right’ rule can be hard, and different biological situations might require different matching rules. Indeed quite a few distinct rules have been proposed in the literature, like, e.g., the *Hamming* distance and the *Manhattan* distance. The first is given by the number of positions in which two strings differ, while the Manhattan distance between two strings is the sum of the distances between their digits [11]. For example, let us fix the two strings ‘54’ and ‘84’. Their Hamming distance is 1 (they only differ in the leftmost symbol), and their Manhattan distance is 3 (obtained as $8 - 5 + 4 - 4$). Yet another definition of distance comes from the so-called *xor rule*. Each symbol in the string is represented as a binary number, and the distance between two strings is computed as the normalized sum of the digits of the xor of the two numbers. This last notion of distance is finer than the Hamming distance, and it is computationally more efficient than the Manhattan rule. The shape spaces that use strings and matching rules are globally called *Hamming spaces*.

Figure 3 shows an example of the use of Hamming spaces. Three proteins A, B and

C with one motif each are reported in the picture. Each motif is represented by an eight-digit string, where each digit can be 1 (drawn as a rectangle) or 0 (drawn as a square). So the motifs of A, B and C are 11010010, 10110001 and 10100101, respectively. Assume that the function $C: \{0,1\}^8 \rightarrow \{0,1\}^8$ maps 0s to 1s and 1s to 0s. We adopt the Hamming distance and compare each pair of strings reading the digits from left to right. The mutual interaction propensities of A, B and C are then given by $d_{AC(B)} = 4$, $d_{AC(C)} = 2$ and $d_{BC(C)} = 6$, where $d_{X(Y)}$ stays for the distance between X and Y . Since the lowest distance value is $d_{AC(C)}$, we can conclude that the two proteins A and C have the greatest interaction propensity in the considered set.

For the sake of clarity, in the above example we made two choices that are not quite realistic from a biological point of view. First, we chose to evaluate strings from left to right, while proteins freely float in the living matter and therefore many other different kinds of interaction are possible. A more concrete model would define the value $d_{X(Y)}$ as the longest stretch of consecutive complementary bits [12]. Second, we assumed a direct map between the distance $d_{X(Y)}$ and the interaction propensity between X and Y . More generally, one would need to define a map between distance and interaction propensity [11].

4 Beta-Binders Presented Graphically

In this section we briefly recall beta-binders and comment on the generalization that allows a direct representation of

define suitable functions that allow them to model cell infection, viral replication, and binding of T cells to infected cells.

The researchers express their confidence that they have taken a first step towards a theory of complex systems built on the formal semantics of programming languages and that this will provide the basis for handling biological systems in the post-genomic era. Furthermore, because biological systems are hierarchical, the approach will allow science to expose the relationships across the macro-, meso- and micro-worlds as a compilation problem.

Conversely, the approach could also lead to new biomimetic computational paradigms and primitives. It helps define new techniques that can handle more complex systems and through an improved understanding of interaction and communication between ‘active’ entities gleaned from the biological models enhance our understanding of complex systems theory in global distributed computing, for instance. Revelations from the application of the Prandi, Priami, and Quaglia approach to the immune system as described through design, analysis and simulation could lead to new concepts in information security – imagine a self-evolving computer network that responds to the context and nature of a security threat and adapts to overcome it.

David Bradley of Sciencebase.com

Fig. 3. Hamming space example.

shape spaces. We resort to a graphical presentation of the language and of its rules. The interested reader is referred to Priami and Quaglia [3] for the mathematical details concerning notation and semantics. In the present paper we just point out the single modification that has to be applied to the original formalism to directly render the notion of distance.

Beta-binders build on the intuition that biological entities have an internal 'process unit' and an 'interface' exposed to the external environment. For example, a protein has a backbone and motifs for interacting with the environment. A cell has a similar structure: it has a membrane whose proteins act as an interface, and a complex internal structure that responds to the external changes. This interpretation of cell is quite limited if we are studying a single cell, but in the context of the study of cellular populations, e.g. in immunology, this vision is acceptable [13]. Furthermore, the computations internal to cells have a high degree of parallelism and it is not surprising that techniques from concurrency theory can be used for representing structural changes of the living matter.

Specifically, the beta-binders formalism encloses mobile processes [14] into active borders. These borders that represent the interface of the described entity

are equipped with typed binders which are used for discriminating between allowed and disallowed interactions with the environment. The processes lying within the borders are made up of a limited number of operators, each corresponding to a distinct possible behaviour. Given a denumerable set of names (channels), the basic syntax of internal processes (ranged over by $P, Q, \dots$) and the semantic meaning associated with the various operators is given as follows:

$\bar{x}(y).P$ can output the name y over x and subsequently act as P ;

$x(y).P$ can perform an input over x , bind the received datum to y , and then act as P ;

$P|Q$ behaves as P in parallel with Q ; the two subprocesses can either run independently or synchronize;

$!P$ behaves as $P|!P$, i.e., it can spawn infinitely many copies of P .

Above, 'synchronization' corresponds to the matching of complementary actions, namely an input and an output over the same channel name. A few more operators are also used. They will be presented later on in this section.

Beta-binders are equipped with an intuitive graphical representation. We now explain the computational rules of the formalism by showing their application to a running example. First consider the fol-

lowing beta-binders process, denoted as S_1 (see schema 1).

System S_1 is composed by three beta-binders processes, called *boxes*: A_1, B_1 , and C_1 . These boxes represent subcomponents that run in parallel, and their distribution in the space is irrelevant (e.g., one could just as well draw box C_1 to the left of A_1). Each box is equipped with a beta-binder (i.e. an interface). For example, box A_1 is given the binder $x: \{a_1, a_2\}$, named x and typed by the set of names $\{a_1, a_2\}$.

Inter-Boxes Communication

In system S_1 , box A_1 can interact with either B_1 or C_1 . This is so because:

- A_1 can perform the input $x(y)$ over the name x of its binder, B_1 can perform the output $\bar{u}(w)$ over the name u of its binder, and, since the types of x and u are not disjoint, this input and output can match.
- Also, the types of x and of the binder v are not disjoint, and the output $\bar{x}(z)$ of A_1 can match the input $v(w)$ of C_1 .

Let us consider the inter-communication between A_1 and B_1 . It consumes the actions $x(y)$ and $\bar{u}(w)$, in the first and in the second box, respectively, and leads to the configuration shown in schema 2.

Note that the information w flowed from box B_1 of S_1 to box A_2 of S_2 , represented by the substitution of the name w

$$S_1 = \begin{array}{ccc} x : \{a_1, a_2\} & u : \{a_1\} & v : \{a_2\} \\ \boxed{x(y).P_1 \mid \bar{x}(z).P_2} & \boxed{\bar{u}(w).Q} & \boxed{v(w).R} \\ (A_1) & (B_1) & (C_1) \end{array} \quad (1)$$

$$S_1 \rightarrow S_2 = \begin{array}{ccc} x : \{a_1, a_2\} & u : \{a_1\} & v : \{a_2\} \\ \boxed{P_1\{w/y\} \mid \bar{x}(z).P_2} & \boxed{Q} & \boxed{v(w).R} \\ (A_2) & (B_2) & (C_1) \end{array} \quad (2)$$

for the occurrences of y in P_1 , written $P_1\{^w/y\}$.

Intra-Boxes Communication

In system S_1 , a communication within box A_1 is made possible as well. It would lead to the configuration shown in schema 3.

In the transformation $S_1 \rightarrow S_3$ we observe an internal modification of the left-most box from A_1 to A_3 . The other two boxes remain unaffected. Given the initial system S_1 , inter-communication and intra-communication are both allowed to occur. This reflects real biological situations. For example, internal modifications of the structure of a protein are in competition with environmental solicitations, like, e.g., the interaction with an enzyme.

Interface Handling

Internal processes are also provided with a limited number of operations for managing box interfaces. The associated syntax and semantics are described below:

hide(x). P

make the binder x invisible then it behaves like P . (When made invisible, x is written x^h .) If the enclosing box has no x -named binder, it sticks.

unhide(x). P

make the binder x^h visible then it behaves like P . (When made visible again, x^h is turned back to x .) If the enclosing box has no x^h -named binder, it sticks.

expose(x , Δ). P

add an x -named binder typed by Δ then it behaves like P .

Consider for instance the box D_1 drawn below (see schema 4).

The execution of the prefix **hide(x)** hides the binder named x and changes its name to x^h . Then the execution of the prefix **expose(z , $\{b_1, b_2\}$)** adds a new beta-binder typed by $\{b_1, b_2\}$ to the box. As a result of this, after two computational steps, D_1 is transformed into D_2 .

Note that a box may be associated with more than one single binder, as it is the case for D_2 above. Indeed, unless other-

wise specified, when talking about the 'binder' of any given box, we refer to the set of all its singular binders. For instance, the binder of D_2 is the set composed of the two elements x^h : $\{a_1, a_2\}$ and z : $\{b_1, b_2\}$.

Box Joining and Splitting

To handle the box structure, beta-binders are provided with operations for joining boxes together and for splitting one box in two. The *join* operation is parametric w.r.t. a function, called f_{join} , and models different possible ways of merging boxes, each of them depending on a distinct instantiation of f_{join} . Let B_1, B_2, B' stay for box binders, and let σ_1, σ_2 represent name substitutions. Then, under the hypothesis that the actual function f_{join} is defined at (B_1, B_2, P_1, P_2) and that $f_{join}(B_1, B_2, P_1, P_2) = (B', \sigma_1, \sigma_2)$, the general pattern of the join transformation can be graphically rendered as shown in schema 5.

The above transformation, just like those illustrated before, can be applied to a subset of a bigger system, leaving the rest

$$S_1 \rightarrow S_3 = \begin{array}{ccc} \begin{array}{c} x : \{a_1, a_2\} \\ \boxed{P_1\{z/y\} \mid P_2} \\ (A_3) \end{array} & \begin{array}{c} u : \{a_1\} \\ \boxed{\bar{u}\langle w \rangle. Q} \\ (B_1) \end{array} & \begin{array}{c} v : \{a_2\} \\ \boxed{v(w). R} \\ (C_1) \end{array} \end{array} \quad (3)$$

$$\begin{array}{ccc} \begin{array}{c} x : \{a_1, a_2\} \\ \boxed{\text{hide}(x). \text{expose}(z, \{b_1, b_2\}). P \mid Q} \\ (D_1) \end{array} & \longrightarrow & \begin{array}{c} x^h : \{a_1, a_2\} \quad z : \{b_1, b_2\} \\ \boxed{P \mid Q} \\ (D_2) \end{array} \end{array} \quad (4)$$

$$\begin{array}{ccc} \begin{array}{c} B_1 \\ \boxed{P_1} \\ (E_1) \end{array} & \begin{array}{c} B_2 \\ \boxed{P_2} \\ (E_2) \end{array} & \longrightarrow & \begin{array}{c} B' \\ \boxed{P_1\sigma_1 \mid P_2\sigma_2} \\ (E') \end{array} \end{array} \quad (5)$$

unaffected. Namely, if the global system were made up of E_1 , of E_2 , and of some other box E_3 , then after the transformation the system would be composed of two boxes: E' and E_3 .

The operation that rules the splitting of boxes is dual to the above joining transformation. If $f_{split}(B, P_1, P_2) = (B_1, B_2, \sigma_1, \sigma_2)$ then a box with binder B and internal process $P_1 | P_2$ is modified in two boxes: each of them with binder B_i and internal process $P_i \sigma_i$, for $i = 1, 2$.

4.1 Integrating Shape Spaces into Beta-binders

Beta-binders offer a natural ground for the integration of shape spaces. Essentially, in other process calculi interactions only depend on the matching of complementary actions (e.g., of an input and an output over the same channel). In beta-binders the above requirement is partially relaxed and, at the level of interfaces, an input over

$x : \Delta$ can match whichever output over $w : \Gamma$, provided that Δ and Γ share some common element.

Here the definition of types and their management is specialized further so as to capture the intuition behind Hamming spaces and string matching rules. In par-

ticular, types become *strings of names*, and the compatibility of types (originally interpreted as nonempty intersection of sets) becomes *distance between strings*.

As observed in section 3, distinct matching rules can best fit different contexts. Hence we adopt the following abstract definition of distance.

Definition 4.1: Given two strings of symbols Γ and Δ over the alphabet $\mathcal{A}$, the **distance** function $\rho(\Gamma, \Delta)$ is a map $\mathcal{A}^n \times \mathcal{A}^m \rightarrow \mathbb{R}$, where n is the length of Γ , and m is the length of Δ .

The definition of the distance function leaves the user free to use different matching rules, leaving the rest of the formal system unaffected. Consider for example the boxes shown in schema 6.

We can set the distance between strings of different lengths to ∞ , and assume symbols to be complementary to themselves. Then, adopting the Hamming distance for strings of the same length, we get $\rho(a_1 a_2 b_1 b_2 a_1, a_1 a_1 b_1 b_1 a_1) = 2$. In a quantitative context this value could be directly used for deriving specific stochastic parameters. In a qualitative view, one can say that the interaction between F_1 and F_2 is allowed only if the distance between the

types of their binders is lower than a given threshold [see 11 for some examples about this]. Indeed, to directly deal with shape spaces, the formal rule defined in Priami and Quaglia [3] for the inter-communication between a box with an elementary binder $x : \Gamma$ and a box with an elementary binder $y : \Delta$ is modified by requiring that:

$$\rho(\Gamma, \Delta) < \text{threshold}$$

where ‘threshold’ is a suitable user-defined value.

5 A Simple Model from the Immune System

We conclude the paper by showing how the above formalism can be applied to model the interactions of a few key players of the immune system.

As an example, we consider a small system composed of a cell, a virus, and a cytotoxic T cell. First, we represent the three actors as boxes with appropriate binders. Then we define suitable instances of the f_{join} and of the f_{split} functions that allow the modelling of cell infection, virus replication, and binding of T cells to infected cells. In passing, we show one of the possible runs of the whole system.

The formal representation of the system is graphically given as in schema 7, where

$\Delta_C = cabbaba$, $\Delta_{V_1} = vbaaaaab$, $\Delta_{V_2} = vabbbabba$, $\Delta_T = tbaaabbbb$, and $C_{act} = !\text{expose}(y, x_1) \cdot \text{expose}(z, x_2)$. Also, for notational convenience, we use the following shorthands: $C = \text{dna}(x_1) \cdot \text{dna}(x_2) \cdot C_{act}$, and $V = !\text{dna}\langle e_{V_1} \rangle \cdot \text{dna}\langle e_{V_2} \rangle$.

Looking at the above specification of C_{act} , note that we use a name, rather than a set, as second parameter of the `expose` ($-, -$) operator. This discrepancy w.r.t. the semantics presented in Priami and Quaglia [3] can be motivated by supposing that some names are taken from a distinguished set in bijection with the set of the typing strings. Under the same assumption, the names e_{V_1} and e_{V_2} transmitted by `Virus` over `dna` are to be thought of as encodings of the types Δ_{V_1} and Δ_{V_2} .

`Cell` represents an eukaryote cell with a site x that expresses its interaction capabilities. The cell machinery is rendered by the input actions over `dna` that, when consumed, trigger C_{act} and hence the exposition of new binders.

`Virus` stays for an intracellular parasite. This kind of parasites consists of an outer cell (*capsid*) made up of proteins and of an interior core containing the genome (DNA or RNA). A virus can enter into a cell and, once inside, it uses the cell machinery to duplicate the genome and to synthesize

proteins. In this way the virus builds a new capsid and a new core, i.e. it duplicates itself. The newly generated virus can exit the cell, while the originator still infects it. The `Virus` box has two sites, the one typed by Δ_{V_1} is used to model cell infection, while the site typed by Δ_{V_2} can be recognized by highly specific lymphocytes (which are missing from the present picture).

`TCell` represents a cytotoxic T cell of the adaptive immune responses. T cells circulate in the body searching for cells that have been infected by external organisms, like viruses. In fact, infected cells display on their surfaces some fragments of the viral proteins. A T cell that recognizes an infected cell kills it, so preventing the diffusion of the virus. T cells are highly specific and hence they require a high affinity with the virus fragment displayed by the infected cell.

The binder types we use in our model are strings that encode the representation of the box they belong to. In the above model, the alphabet of the typing strings is $\{c, v, t, a, b\}$. The first symbol of the string encodes the owner of the binder associated with that type: c stands for `Cell`, v for `Virus`, and t for `TCell`. The rest of any typing string that actually represents the shape of the binder is made up of as and bs .

We assume that the complementarity function $C: A^m \rightarrow A^m$ behaves like the identity on the elements of the set $\{c, v, t\}$ and maps as to bs and bs to as . Letting $H(-, -)$ denote the Hamming distance, we now define the distance function as follows:

$$\rho(x\Delta, y\Gamma) = \text{if } m = |\Delta| = |\Gamma| \text{ and } \Delta \in \{a, b\}^m \text{ and } \Gamma \in \{a, b\}^m \\ \text{then } H(\Delta, C(\Gamma)) \text{ else } \max\{|\Delta|, |\Gamma|\}.$$

Note that the first symbol of each of the two strings, representing the class of the binder rather than its shape, is ignored. Also observe that $\rho(\Delta_C, \Delta_{V_1}) = H(abbaba, C(baaaaab)) = 1$, meaning that the affinity between the binder of `Cell` and the virus binder named y is high.

We now complete the specification of our model by defining the functions that rule the joining and splitting of boxes. In what follows, the metavariables $B^*, B_1^*, B_2^*, \dots$ are used to denote possibly empty box binders.

The first rule, driven by an instance of f_{join} called f_{joinVC} , can be graphically rendered as shown in schema 8.

The rule states that, if in the global system there are two boxes which exhibit binders typed by $v\Gamma$ and by $c\Delta$, respectively, and if the distance between these two

$$(f_{joinVC}) \quad \text{if } \rho(v\Gamma, c\Delta) < 3 \quad \begin{array}{c} B_1^* \quad y : v\Gamma \\ \boxed{P_1} \end{array} \quad \begin{array}{c} B_2^* \quad x : c\Delta \\ \boxed{P_2} \end{array} \rightarrow \begin{array}{c} B_2^* \quad x : c\Delta \\ \boxed{P_1 \mid P_2} \end{array} \quad (8)$$

$$S1 \rightarrow \begin{array}{c} x : \Delta_C \\ \boxed{C \mid V} \end{array} \quad \begin{array}{c} w : \Delta_T \\ \boxed{T} \end{array} \rightarrow \rightarrow \rightarrow \begin{array}{c} x : \Delta_C \quad y : \Delta_{V_1} \quad z : \Delta_{V_2} \quad w : \Delta_T \\ \boxed{C_{act}\sigma \mid V} \end{array} \quad \boxed{T} \quad (S2) \quad (9)$$

types is less than 3, then the two boxes can be joined together and the resulting box has the same binder as the $c\Delta$ -typed box. When applicable, this rule models *cell infection*. In particular, starting from the global system S1, we get the representation shown in schema 9, where $\sigma = \{e_{V_1}/x_1, e_{V_2}/x_2\}$. Above, the first computational step is due to the f_{joinVC} transformation that makes the virus genetic material V enter the cell. The following computational steps correspond to intra-communications over *dna* and to the subsequent exposition of the received binder types.

Referring to S2, observe that $C_{act}\sigma = !\text{expose}(y, e_{V_1}) \cdot \text{expose}(z, e_{V_2})$ can keep exposing the virus proteins an unlimited

number of times. So the cell never gets ‘consumed’ by the virus. As outlined in Priami and Quaglia [3], a slight refinement of the formal model could take care of this aspect and limit the number of possible replications of the process $\text{expose}(y, e_{V_1}) \cdot \text{expose}(z, e_{V_2})$.

We now define the rules for *virus replication* and for the *binding of T cells* to infected cells, which are driven by $f_{splitVC}$ and f_{joinCT} respectively (schema 10).

We conclude this section by showing one of the possible computations that can be automatically derived from S2. The computation reflects the application of the following sequence of transformations: $f_{splitVC}$ exposition of the Δ_{V_1} and Δ_{V_2} -

typed binders by the infected cell, and f_{joinCT} transformation (schema 11).

5.1 Compositionality to Hammer Complexity

One of the main advantages in using formal methods and process calculi theory comes from *compositionality*. Compositionality means that it is possible to develop different pieces of a model separately and then putting them all together following mathematical rules. The underlying idea is to see biomolecular (as well as cellular) systems as a set of elementary components from which complex entities are constructed. This introduces a new paradigm with respect to ‘classical’ complex bi-

$$(f_{splitVC}) \quad \begin{array}{c} B \quad y : v\Gamma \quad z : v\Delta \\ \boxed{C_{act}\sigma \mid V} \end{array} \rightarrow \begin{array}{c} B \\ \boxed{C_{act}\sigma} \end{array} \quad \begin{array}{c} y : v\Gamma \quad z : v\Delta \\ \boxed{V} \end{array} \quad (10)$$

$$(f_{joinCT}) \quad \text{if } \rho(t\Gamma, v\Delta) < 2 \quad \begin{array}{c} B_1^* \quad w : t\Gamma \\ \boxed{P_1} \end{array} \quad \begin{array}{c} B_2^* \quad y : v\Delta \\ \boxed{C_{act}\sigma} \end{array} \rightarrow \begin{array}{c} B_1^* B_2^* \quad w^h : t\Gamma \\ \boxed{P_1 \mid C_{act}\sigma} \end{array}$$

$$\begin{array}{l} S2 \rightarrow \begin{array}{c} x : \Delta_C \quad w : \Delta_T \quad y : v\Gamma \quad z : v\Delta \\ \boxed{C_{act}\sigma} \quad \boxed{T} \quad \boxed{V} \end{array} \\ \rightarrow \rightarrow \begin{array}{c} x : \Delta_C \quad y : \Delta_{V_1} \quad z : \Delta_{V_2} \quad w : \Delta_T \quad y : v\Gamma \quad z : v\Delta \\ \boxed{C_{act}\sigma} \quad \boxed{T} \quad \boxed{V} \end{array} \\ \rightarrow \rightarrow \begin{array}{c} x : \Delta_C \quad y : \Delta_{V_1} \quad z : \Delta_{V_2} \quad w^h : \Delta_T \quad y : v\Gamma \quad z : v\Delta \\ \boxed{C_{act}\sigma \mid T} \quad \boxed{V} \end{array} \end{array} \quad (11)$$

ological system modelling. Indeed immunologists are moving in this direction, leaving differential equation models for agent-based model [15] or stochastic stage-structured model [13]. But the new models lack in strong mathematical backgrounds, which seems a mandatory requirement for modelling, analyzing and sharing biological knowledge.

In this section we realize this idea developing a simple model of an antibody and showing how it can be integrated in the model we presented above.

An antibody is a molecule that has a specialized portion for identifying other molecules called *paratope*. Paratope has a defined shape that characterizes the molecules that it can interact with. Each foreign molecule (e.g., viruses) presents a certain relief or pattern that can be recognized with various degrees of precision by complementary patterns or paratopes located on antibody molecules. When an antibody A recognizes a virus V , it happens that A binds V preventing infection. More-

over, the newly generated complex $A-V$ has a new binder that helps phagocytic cells. For instance, the capsule that surrounds pneumococci protects them from phagocytosis. If the appropriate antibodies are present in the body, they combine with the capsule and now the pneumococci can be ingested [16].

The formal representation of an antibody is graphically described below:

where $\Delta_A = pabbbba$. Also we have to define the function that drives the joining of a virus and an antibody (schema 12).

The above rule states that, if there is an antibody that is able to recognize a virus, then the antibody binds it. The new complex is no more able to enter a cell and

moreover a new binder $x: m\Delta_M$ is added. This binder has high affinity with phagocytic cells helping the complex ingestion.

Once the antibody model is defined we can extend the system ($S1$) leading to the representation shown in schema 13.

This system can perform the same sequence of transformations depicted in the previous section, without any differences. Moreover the antibody can bind to the virus so preventing cell infection (schema 14).

Note that the complex (Virus-AntyB) is no longer able to interact with (Cell). Moreover, it is possible to automatically infer all the possible future behaviours of the system, giving a powerful methodology for investigating complex systems.

6 Conclusions and Perspectives

We presented a formalism to model complex (biological) systems. The main objective is to determine the suitable abstraction to have a formal description of systems on top of which analysis and sim-

$$(f_{join_{VA}}) \quad \text{if } \rho(v\Gamma, a\Delta) < 2 \quad \begin{array}{c} z : v\Gamma_1 \quad y : v\Gamma_2 \\ \hline \boxed{P_1} \end{array} \quad \begin{array}{c} B_1^* \quad x : p\Delta \\ \hline \boxed{P_2} \end{array} \rightarrow \begin{array}{c} z : v\Gamma_1 \quad B_1^* \quad x : m\Delta_M \\ \hline \boxed{P_1 \mid P_2} \end{array} \quad (12)$$

$$\begin{array}{ccccccc} x : \Delta_C & y : \Delta_{V_1} & z : \Delta_{V_2} & w : \Delta_T & k : \Delta_A & & \\ \hline \boxed{C} & \boxed{V} & \boxed{T} & \boxed{A} & & & \\ \text{(Cell)} & \text{(Virus)} & \text{(TCell)} & \text{(AntyB)} & & & \end{array} \quad (S1') \quad (13)$$

$$S1' \rightarrow \begin{array}{ccc} x : \Delta_C & y : \Delta_{V_2} \quad z : \Delta_M & w : \Delta_T \\ \hline \boxed{C} & \boxed{V \mid A} & \boxed{T} \\ \text{(Cell)} & \text{(Virus+AntyB)} & \text{(TCell)} \end{array} \quad (14)$$

ulation can be implemented. We selected here the biological applicative domain and in particular the immune systems because handling these phenomena could help us to control, design and program complex systems as well as to reconstruct systems from incomplete data. The main achievement of the present work with respect to the definition of beta-binders is the inclusion in the formalism of the representation of shape spaces. This enhancement shows how the formalism proposed is flexible in specifying systems at different levels of abstraction. We also worked out the main feature of compositionality showing how a system can be specified incrementally by simply adding new descriptions to the ones already produced when new information becomes available.

We are confident that this is a first step towards a theory of complex systems whose main brick is formal semantics of programming languages for concurrency (specifically process calculi). The study of process calculi and their definition since the beginning inspired by biological phenomena could lead to new biomimetic computational paradigms and primitives. The main goals of the new specification languages are to implicitly handle complexity in their semantic definition and to model, analyze, simulate and compare different systems. We feel this step is very important because the major big step in research has been performed in the past when difficult concepts have been abstracted into good linguistic frameworks. Furthermore, the hierarchical nature of biological systems allows us to exploit the relation between the macro-world, meso-world and micro-world as a compilation problem.

The above-mentioned strategy will have an impact on life science by helping biologists with their research, but also on computer science defining new techniques able to handle systems more complex than the current ones. Furthermore, the abstraction of biological models in terms of

interaction/communication of active entities can help enhance the understanding of many fields of computer science, besides of course complex systems theory. We mention here just two of them because they are of interest nowadays.

Global computing and global computer have properties similar to biological systems because they are made up of autonomous and widely dispersed entities not centrally controlled, they include mobile code and appliances whose configurations vary over time and have incomplete information on the environment in which they work. If we can devise formalisms to handle biological systems, then we have good chances to improve the global computing field as well.

The particular application of immune system design, analysis and simulation could lead to new ideas for developing an information security framework that are self-adapting to the new context in which a treat is ongoing.

Summing up, we hope that the development of the present paper could lead to a larger applicability of the formalism presented in many different fields. In fact the abstraction molecules as processes and interaction as communication can be applied to any system whose evolution step is an interaction of some kind.
